Abstract

The hygroscopicity of mineral aerosol samples has been examined by three independent methods: diffuse reflectance infrared Fourier transform spectroscopy, thermogravimetric analysis and differential mobility analysis. All three methods allow an evaluation of the water coverage of two samples, CaCO_3 and Arizona Test dust, as a function of relative humidity. For the first time, a correlation between absolute gravimetric measurements and the other two (indirect) methods has been established. Water uptake isotherms were reliably determined for both solids which at 298 K and 80% relative humidity exhibited similar coverages of ~ 4 monolayers. However, the behaviour at low relative humidity was markedly different in the two cases, with Arizona Test Dust showing a substantially higher affinity for water in the contact layer. This is understandable in terms of the chemical composition of these two materials. The mobility analysis results are in good accord with field observations and with our own spectroscopic and gravimetric measurements. These findings are of value for an improved understanding of atmospheric chemical processes.

1. Introduction

The physicochemical properties of aerosol particles affect the radiative balance and chemistry of the Earth's atmosphere. The hygroscopic properties of aerosol particles are important both to their direct and indirect effects on the Earth's radiation budget. Aerosols affect the radiative balance of the Earth by scattering and absorbing solar radiation (Kaufman et al., 2002). The single scattering albedo of a particle depends on its size and refractive index, both of which are strong functions of the aerosol water content.

Cloud droplets form via the condensational growth of aerosol particles, and the hygroscopic properties of the aerosol surface control the rate of activation of aerosol particles to form cloud droplets. The optical properties and lifetime of the resulting

cloud depend on the hygroscopicity of the initial aerosol on which the cloud droplets form (Charlson et al., 1992).

Aerosols also provide a sink for reactive gases as well as a substrate for chemical transformation (Ravishankara and Longfellow, 1999), and aerosol water content has been shown to affect the rate of uptake of soluble gases (Hallquist et al., 2003). Measurements of hygroscopic growth and associated water content are therefore necessary to understand the radiative and chemical effects of tropospheric aerosol species.

Mineral dust aerosol is an important component of the atmosphere, comprising the fine particles of crustal origin advected from arid regions and consisting primarily of silica and silicate minerals. It is estimated that between 1000 and 3000 Tg/year are emitted into the atmosphere, primarily in the Northern Hemisphere from the Sahara, the Arabian peninsula and central Asia (Tegen and Fung, 1994). The fine, sub-10 μm fraction has an atmospheric lifetime of several days and can be transported over thousands of kilometres (Savoie and Prospero, 1982). The short lifetime and uneven distribution of sources can lead to strong spatial and temporal variability in radiative forcing, particularly over the North Atlantic Ocean and South East Asia (Garrett et al., 2003). Mineral dust can also affect the atmospheric chemistry through removal of traces gases such as SO_2 and HNO_3 (Hanke et al., 2003) and it is known that mineral dust particles are frequently coated with sulphate and other electrolytes (Li-Jones and Prospero, 1998) as a result of atmospheric processing. The hygroscopic properties of aged aerosols are therefore expected to differ significantly from those of a freshly-emitted aerosol, with important consequences for the radiative and chemical properties.

We report water uptake for two classes of aerosol: calcite, i.e. CaCO_3 , and Arizona Test Dust. Calcite is an important component of Saharan dust, comprising up to 30% of the aerosol mass (Loyepilot et al., 1986). The water content of calcite particles is important in the atmospheric oxidation of SO_2 that proceeds via the formation of a calcium sulfate hemihydrate (Dentener et al., 1996).

In the work reported in this article, the water uptake was measured by two different techniques: diffuse reflectance Fourier transform spectroscopy (DRIFTS), and thermo-

gravimetric analysis (TGA). Additionally, the size distribution of a laboratory-generated aerosol, and therefore approximate water content, was measured using a scanning electrical differential mobility analyser (DMA).

2. Experimental Methods

5 2.1. Sample preparation and characterization

The samples analyzed were Arizona Test Dust (nominal 0–3 μm fraction, Powder Technology Inc., Minnesota, USA) and calcite (Specialty Minerals Ltd, Birmingham, UK, nominal diameter ~ 70 nm). Prior to DRIFTS and TGA experiments the samples were conditioned for one hour at 120°C under helium to remove any species adsorbed on
10 the surface. Surface area analysis was performed using a Micromeritics Gemini BET analyser.

2.2. Diffuse reflectance Fourier Transformed spectroscopy (DRIFTS)

DRIFTS experiments were performed with a Perkin-Elmer GX2000 spectrometer equipped with a liquid nitrogen cooled MCT detector. The DRIFTS sample (Collector II,
15 Thermo Spectra-Tech) was installed in a controlled atmosphere cell that also allowed control of the sample temperature. The detector and sample areas of the spectrometer were purged with N_2 to reduce the contribution of atmospheric CO_2 and H_2O . Accurate flows of humid gas were obtained using mass flow controllers (MKS) to pass a controlled proportion of the total gas through high purity deionized water. Relative
20 humidity (RH) was measured with a humidity probe (Vaisala Humitter) and difference spectra were acquired at 25°C with a resolution of 4 cm^{-1} (average of 100 scans). Background spectra of the conditioned sample were taken under a flow of helium at 25°C.

2.3. Thermogravimetric analysis (TGA)

TGA experiments were performed using a Mettler-Toledo TGA/SDTA851e with an accuracy of $\pm 1 \mu\text{g}$. The balance and sample compartments were purged with nitrogen. The weight of the sample was measured continuously under isothermal conditions. The humidity of the purge gas was increased in steps, the balance output being allowed to stabilise between each step. The experiment was repeated without the sample present to correct for water adsorption to the sample holder and balance apparatus.

2.4. Aerosol growth measurements

Hygroscopic growth factors are derived from size distributions measured as a function of relative humidity (RH) by calculating the ratio of mean particle diameter of an aerosol distribution at a given RH to that of similar particles at a RH below 30%. Aerosols were generated using a slow-flow nebulizer system, based on the design of Lindqvist et al. (1982). The nebulizer holds a continuously stirred suspension of particles in distilled water, and a peristaltic pump generates a flow of approximately 2 ml min^{-1} through the hypodermic needle of the nebulizer system. At the exit of the needle, the flow of liquid meets a fast flow of N_2 (0.5–1.5 slm), generating an aerosol with a number density of approximately $1 \times 10^6 \text{ particles cm}^{-3}$.

For certain measurements, the aerosol stream was dried to $<2\%$ RH by passing the flow through a pair of diffusion driers, which contain a clear channel around which a silica gel/cobalt chloride drying agent is packed. The relative humidity of the aerosol stream was controlled by the addition of a flow of humidified nitrogen. With the driers in the flow stream, a final RH of between 2 and 70% can be generated. When the driers are bypassed, a range of 30–82% RH is accessible. The aerosol stream was passed to a Pyrex conditioner and then to the DMA (Hauke, VIE-EMS-08). Size distributions are calculated by proprietary software that corrects for the effects of multiple charging, assuming spherical particle shape.

Aerosols were generated from suspensions in distilled water of calcite particles and

Arizona Test Dust. The calcite particles were used as supplied, while the ATD sample was filtered using Fisherbrand QT 260 filter paper, and the filtrate used in the nebulizer – a procedure found to give the most stable operation. Filtration reduced the concentration of dust in the suspension from 20 mg cm^{-3} to 10.6 mg cm^{-3} in the case of ATD, a reduction of 47%.

3. Results

3.1. Water uptake on calcium carbonate

Adsorption of water vapour onto the CaCO_3 surface was measured at room temperature by means of DRIFTS: the integrated intensity the O-H stretching region (ca. $3000\text{--}3700 \text{ cm}^{-1}$, see inset Fig. 1) provides a measure of the amount of water on the surface (Saliba et al., 2001).

The peak in this region is a combination of vibrational modes: symmetric stretch at 3423 cm^{-1} and asymmetric stretch at 3253 cm^{-1} . The absorbance of these modes is suitably strong to monitor water adsorption on the surfaces of the particles (Goodman et al., 2001).

The reflected radiation in DRIFTS is dependent on many factors including: particle dimension, packing density and homogeneity among others (Armaroli et al., 2004). In addition, unlike transmission FTIR, DRIFTS shows no linear relation between band intensity and concentration. Gaining quantitative information from the spectra is non-trivial as the Beer-Lambert law used in transmittance is not applicable. However, Kubelka-Munk theory can be applied to improve the linearity of the dependence of signal intensity upon concentration (Armaroli et al., 2004).

Figure 1 shows the water adsorption isotherm obtained after applying the Kubelka-Munk function to the DRIFTS data. The isotherm exhibits type III characteristics indicative a low adsorption enthalpy in the contact layer: the absence of a clear indication of the monolayer point makes coverage quantification problematic. Accordingly, in or-

Water uptake on mineral surfaces

R. J. Gustafsson et al.

der to obtain absolute values of surface coverage thermogravimetric analysis (TGA) was used to measure the mass of adsorbed water as a function of relative humidity (Fig. 2, closed circles). Knowing the surface area of the sample ($17.8 \text{ m}^2 \text{ g}^{-1}$ from BET) the mass of water adsorbed was converted into coverage in terms of water monolayers by making a reasonable assumption about the size of the adsorbed water molecule (14.3 \AA^2 , Hackerman and Hall, 1958). On this basis, we calculate that one monolayer is absorbed at $\sim 55\%$ RH, adsorption proceeding up to ~ 4.5 monolayers at 80% RH. The shape of the corresponding isotherm (Fig. 2) resembles that of the DRIFTS-derived isotherm (Fig. 1) and Fig. 3 shows the correlation between TGA and DRIFTS results. This is linear at sub-monolayer coverage, but at higher coverages DRIFTS appears to underestimate the amount of adsorbed water.

3.2. Hygroscopic growth of calcium carbonate aerosol

The calcite aerosol was found to have a bimodal size distribution, which could be represented as the sum of two log-normal distributions of the form:

$$\frac{dN}{d \ln D} = \frac{N}{\sqrt{2\pi} \ln \sigma_g} \exp \left(-\frac{(\ln D - \ln D_{pg})^2}{2 \ln^2 \sigma_g} \right), \quad (1)$$

where D is the particle diameter, D_{pg} the median diameter of the distribution and σ_g the geometric standard deviation. At 5% RH, values of D_{pg} of 55 nm and σ_g of 10 were obtained for smaller of the two modes, while for the larger mode, $D_{pg}=260 \text{ nm}$ and $\sigma_g=4$. We consider that the larger mode is most likely produced by particle agglomeration occurring within the suspension used in the nebulizer. Because of the uncertainty regarding the particle morphology of this larger aerosol mode, its behaviour will not be discussed further.

The median diameter of the smaller mode was found to increase with increasing RH. Figure 4 shows the growth, plotted as $D_{pg}(\text{RH})/D_{pg,0}$ where $D_{pg,0}$ is the average “dry” median diameter, derived from measurements over the range $0\text{--}30\%$ RH. At 80% RH,

a growth factor of 1.09 ± 0.02 is measured.

3.3. Water uptake on Arizona test dust

The experiments were repeated on Arizona Test Dust (ATD) under the same conditions as used for calcite. Note that the TGA-derived isotherm (Fig. 3) is markedly different to that for CaCO_3 . In the present case a shoulder is clearly apparent indicating a higher enthalpy of adsorption into the contact layer. At sufficiently high RH ($\sim 70\%$) where multilayer formation is well developed (~ 2.5 layers) and the influence of the underlying solid surface reduced, the calcite and ATD isotherms converge, as would be expected. At $\sim 80\%$ RH the coverage corresponds to ~ 4 monolayer for both samples. In the sub-monolayer range, the two isotherms are markedly divergent, reflecting the stronger water-ATD interaction in the contact layer, compared to water- CaCO_3 . In passing, we note that the (physically reasonable) calculated coverages that characterize the monolayer and multilayer regimes of these isotherms validate our method of quantifying the TGA data. As in the case of CaCO_3 , the DRIFTS isotherm (Fig. 5) qualitatively resembles the TGA isotherm results but the two diverge at higher RH to non-linearities in the spectral response.

3.4. Hygroscopic growth of Arizona Test Dust aerosol

As for the calcite particles, the aerosol generated from a suspension of Arizona Test Dust was found to be bimodal. At 5% RH, average values of 61 nm and 270 nm were obtained for D_{pg} in the two modes, with corresponding values of 10 and 31 for σ_g . Figure 6 shows the hygroscopic growth factors of the small mode – slightly lower growth is observed, compared to the calcite particles. At 80% RH, a growth factor of 1.14 ± 0.07 is observed.

4. Discussion

The results described above represent the first comparative study of water uptake on mineral aerosols using three independent techniques: TGA, DRIFTS and DMA. Previous studies made use of Knudsen cell reactors (Seisel et al., 2004) to examine water uptake on mineral surfaces, the relative humidity range employed in such reactors being typically below 1%. Given that most of the troposphere is characterized by 20–90% RH, such measurements are unlikely to be of substantial relevance for atmospheric studies. Other techniques have also been used to investigate water adsorption on mineral surfaces, including transmittance-FTIR (Al-Abadleh et al., 2003) and attenuated total reflectance spectroscopy (ATR-FTIR) (Al-Abadleh et al., 2005; Al-Hosney and Grassian, 2005). The underlying difficulty with these methods is the lack of an absolute calibration. This makes it desirable to verify such results (Al-Abadleh et al., 2005; Al-Abadleh et al., 2003) by independent techniques. Our measurements of water adsorption on CaCO_3 by TGA (Fig. 3) show that monolayer coverage occurs at 55% relative humidity, in good agreement with ATR-FTIR data (Al-Hosney and Grassian, 2005). TGA allowed reliable determination of the absolute isotherm over a wide relative humidity range, whereas the spectroscopic results obtained by Grassian et al. (2003, 2005) permitted only identification of the monolayer coverage point and not a quantitative evaluation of multilayer growth with increasing RH.

Arizona test dust consists principally of silica (~70%) and alumina (~20%) with small amounts of other minerals (oxides of iron, titanium, calcium etc.). In accord with this, our results for Arizona Test Dust do not differ significantly from published results for water uptake on silica and alumina powders (Goodman et al., 2001).

In order to rationalize the weaker interaction of water with CaCO_3 compared to Arizona Test Dust at low relative humidity, it is necessary to consider at the chemical interactions that occur at the solid/liquid interface. The interaction of silica (which dominates in Arizona Test Dust) with water are well understood (Papirer, 2000). It is thought that ~3 layers of water interact strongly with the surface via hydrogen-bonding interac-

Interactive Discussion

tions involving the surface-capping silanol groups (Saliba et al., 2001). Higher layers behave essentially as liquid water.

The mechanisms of water interaction with calcite surfaces have been studied by several groups (Al-Hosney and Grassian, 2005; Stipp, 1999; Stipp et al., 1994). CaCO_3 surfaces exposed to water vapour form CO_3H^- and OH^- surface groups (Stipp, 1999), the resulting $\text{Ca}(\text{OH})(\text{CO}_3\text{H})$ giving rise to enhanced hydrophilic properties and facilitating further water adsorption. It is suggested that at <50% RH water forms 2-D islands with 3-D islands appearing at higher humidity (Al-Hosney and Grassian, 2005).

The isotherms obtained by TGA (Fig. 2) were used to calculate enthalpies of adsorption. The values so obtained (from the corresponding BET parameters) were 45.7 kJmol^{-1} for calcite and 52.2 kJmol^{-1} in the case of Arizona Test Dust. The difference in adsorption enthalpies and the consequent difference in isotherms observed for these two samples (Fig. 2) reflects the different interaction strengths of the two types of surface hydroxylated groups with adsorbed water. The higher electronegativity of Si compared to Ca increases the polarity of the $-\text{OH}$ group which in turn gives rise to stronger H-bonding in Arizona Test Dust. Thus the substantial differences in the early stages of water uptake between carbonate and ATD samples reflects the difference in chemical composition of two solids.

4.1. DMA results

As far as we are aware, this is the first laboratory determination of the hygroscopic properties of mineral dust aerosol. Hygroscopic growth factors were observed to increase monotonically with increasing RH over the range 0–80%, with similar growth factors (~ 1.10) being measured for both ATD and CaCO_3 aerosol at 80% RH.

There have been only a few atmospheric observations relating to the hygroscopic growth of mineral dust aerosol. Carrico et al. report hygroscopic growth factors derived from measurements of the radiative properties of aerosol during the ACE–ASIA campaign (Carrico et al., 2003). The ratios of total light scattering coefficients at 550 nm were used to derive hygroscopic growth factors, which during dust-dominated events,

EGU

were found to be in the range 1.18 to 1.39, although there are indications that this value contains a contribution from an electrolyte component. Li-Jones et al. (1998) measured hygroscopic growth factors for mineral dust particles advected over the Atlantic Ocean. Aerosol scattering coefficients were measured using an integrating nephelometer and growth factors of 1.0 to 1.1 were estimated using data from periods of high dust concentration.

The data (Figs. 4 and 6) were fitted to a function of the form:

$$\frac{D}{D_0} = \left(1 - \frac{RH}{100}\right)^{-\gamma} \quad (2)$$

fits of the hygroscopic growth factors to the above function gave $\gamma=0.053$ and 0.039 for calcite and Arizona Test Dust respectively, with estimated errors of 0.01 . The fitted functions are shown as solid lines in the figures. From the fitted functions, growth factors of 1.09 and 1.06 are derived, equivalent to diameter changes of 5.0 and 3.7 nm respectively.

However, the use of hygroscopic growth factors for a solid aerosol particle is somewhat misleading because the particle is unable to absorb water into the bulk and condensation is a purely surface phenomenon. The observed growth factors are perhaps better expressed as the corresponding changes in particle diameter.

While the conversion of changes in (mobility derived) particle diameter to surface coverage is not straightforward, being complicated by uncertainties arising from changes in particle shape (which affects mobility) and of the molecular diameter of water on the surface, an estimate of surface coverage may be made using these measurements. Taking the area of an adsorbed water molecule as 14.3 \AA^2 (Hackerman and Hall, 1958) and assuming a flat adsorption geometry, a molecular diameter of 420 pm is derived. Thus a change in particle diameter of 5 nm, as measured for calcium carbonate, is equivalent to a coverage of 6 ML , in broad agreement with the TGA and DRIFTS data within the experimental uncertainties. In the case of ATD, a coverage of 4 ML is derived in excellent agreement with the surface experiments.

5. Conclusions

1. Arizona Test Dust and CaCO_3 show markedly different water uptake characteristics over the RH range 0 – 80%. These differences in behaviour are understandable in terms of differences in specific interactions at the solid/liquid interface.
2. TGA provides a reliable quantitative measure of water uptake over the entire RH range enabling relatively unambiguous identification of the monolayer point. DRIFT spectra scale linearly with TGA data at low RH, but diverge significantly at high RH.
3. Our laboratory measurements of hygroscopic growth factors are in accord with both field measurements and with our spectroscopic and gravimetric results. The results indicate moderate hygroscopicity of the mineral dusts, and provide important new data of relevance for the calculation of the rate of uptake of soluble gases by mineral aerosol and the radiative properties of these particles.
