Abstract

Brecciated and fractured peridotites with a carbonate matrix, referred to as *ophicalcites*, are common features of mantle rocks exhumed in passive margins and mid-oceanic ridges. Ophicalcites have been found in close association with massive peridotites, which form the numerous ultramafic bodies scattered along the North Pyrenean Zone (NPZ), on the northern flank of the Pyrenean belt. We present the first field, textural and stable isotope characterization of these rocks. Our observations show that Pyrenean ophicalcites belong to three main types: (1) a wide variety of breccias composed of sorted or unsorted millimeter-to meter-sized clasts of fresh or oxidized ultramafic material, in a fine-grained calcitic matrix; (2) calcitic veins penetrating into fractured serpentine and fresh peridotite; and (3) pervasive substitution of serpentine minerals by calcite. Stable isotope analyses (O, C) have been conducted on the carbonate matrix, veins and clasts of samples from 12 Pyrenean ultramafic bodies. We show that the Pyrenean ophicalcites are the product of three distinct genetic processes: i) pervasive ophicalcite resulting from relatively deep and hot hydrothermal activity; ii) ophicalcites in veins resulting from tectonic fracturing and cooler hydrothermal activity; and iii) polymictic breccias resulting from sedimentary processes occurring after the exposure of subcontinental mantle as portions of the floor of basins which opened during the mid-Cretaceous. We highlight a major difference between the Eastern and Western Pyrenean ophicalcites belonging respectively to the sedimentary and to the hydrothermal types. Our data set points to a possible origin of the sedimentary ophicalcites in continental endorheic basins, but a post-depositional evolution by circulation of metamorphic fluids or an origin from relatively warm marine waters cannot be ruled out. Finally, we discuss the significance of such discrepancy in the characteristics of the NPZ ophicalcites in the frame of the variable exhumation history of the peridotites all along the Pyrenean realm.

I. Introduction

During uplift and exhumation of the sub-continental mantle, the peridotites are commonly serpentized through interactions with fluids, with direct consequences on their bulk density and their rheological, seismic, gravimetric and magnetic properties (Brun & Beslier 1996; Boschi et al. 2006). In oceanic and passive margin environments, besides serpentization, the peridotites show evidence of carbonation expressed through the occurrence of a bimodal, ultramafic and carbonate association known as ophicalcites or ophicarbonates (Spooner & Fyfe 1973; Bonatti et al. 1974; Dietrich et al. 1974; Gianelli & Principi 1977; Ohnenstetter 1979; Lemoine 1980; Cortesogno et al. 1981; Lagabriele & Cannat 1990). More recently, the carbonation of the exhumed mantle rocks has been clearly described as the last event affecting faulted rocks uprising along oceanic detachment faults at the axis of slow-spreading ridges (Picazo et al. 2012).

Ophicalcites were first discovered in the Ligurian Alps (Bonney 1879), and then described in many ophiolite sequences (see Artemyev & Zaykov 2010 and Bogoch 1987 for a comprehensive historical literature on ophicalcites). Ophicalcites commonly display large variations in the proportions of ultramafic and carbonate material. They range from in-situ fractured peridotites with carbonate infill, through clast-supported breccias with multiple generations of carbonate infilling and internal sediments, to matrix-supported breccias. Lemoine et al. (1987) distinguish two main types of ophicalcite. Ophicalcite type 1 (OC1) is represented by massive serpentinites exhibiting a dense mesh of calcite-infilled fractures. Ophicalcite type 2 (OC2) refers to sedimentary breccias having a calcitic matrix, often deposited above ophicalcite of type 1. The clasts comprise sorted or unsorted millimeter- to meter-sized fresh or oxidized ultramafic fragments. In some cases, exotic clasts of gabbroic or basaltic composition can be observed. The matrix of OC2 is either a fine-grained calcitic

sediment or a cement consisting of sparry calcite. It varies in color from red to pink and gray to green, depending on the chlorite or hematite content; sparry calcite is generally white. Opicalcites often record a polyphase history, revealed by different generations of cements and sediment infill, which can be highlighted by color changes, and bimodal grain distribution (Abbate et al. 1970; Bonatti et al. 1974; Bernoulli & Weissert 1985; Lemoine et al. 1987; Früh-Green et al. 1990).

Because of the wide variety of opicalcites and their occurrence in different oceanic or continental margin settings, it is important to recall that the term opicalcite does not refer to a genetic process, but to a generic rock-type. Among the processes invoked for their formation one group refers to endogenic evolution, involving various deep seated phenomena such as: (1) mantle originated gas seeps (Bonatti et al. 1974; Haggerty 1991; Kelemen et al. 2004); (2) magmatic intrusions (Cornelius 1912; Bailey & McCallien 1960); (3) contact and regional metamorphism (Peters 1965; Trommsdorff et al. 1980) and (4) hydrothermal fluid interactions (Cornelius 1912; Lavoie & Cousineau 1995; Artemyev & Zaykov 2010). Another group refers to surficial processes involving mechanical mixing of carbonates and ultramafic rocks through tectonic crushing, sedimentary reworking and gravity-driven infilling of veins and fractures (Bortolotti & Passerini 1970; Knipper 1978; Bernoulli & Weissert 1985; Früh-Green et al. 1990; Treves & Harper 1994; Treves et al. 1995; Knipper & Sharas'kin 1998).

In the French Pyrenees, opicalcites have been reported in some ultramafic bodies associated with mid-Cretaceous basins and recently re-interpreted as resulting from mantle exhumation during Mid-Cretaceous rifting (Lagabriele & Bodinier 2008; Lagabriele et al. 2010; Jammes et al. 2009; Clerc et al. 2012). In order to document and to characterize the variable typology of opicalcites and to decipher their origin with respect to exhumation processes, we have performed a comprehensive field, petrological and geochemical study of samples taken throughout the Pyrenees (fig. 1). We identify three types of opicalcites related to three

distinct genetic processes: i) pervasive opicalcite resulting from replacement of ultramafic minerals due to relatively deep and hot hydrothermal activity, ii) opicalcites as veins resulting from tectonic fracturing and cooler hydrothermal activity and iii) polymictic breccias resulting from syn-sedimentary processes. The first two types record the activity associated with the final emplacement of the peridotites, whereas the last one is associated with the final exhumation of mantle rocks as portions of the basement of newly formed basins.

II. Geological setting of the ultramafic Pyrenean bodies:

The Pyrenees are a narrow, 400 km long continental fold and thrust belt resulting from the collision of the northern edge of the Iberian Plate and the southern edge of the European Plate during the late Cretaceous to Tertiary (Choukroune & ECORS Team 1989; Muñoz 1992; Deramond et al. 1993; Roure & Combes 1998; Teixell 1998). Triassic and Jurassic aborted rifting events predated the development of a major Cretaceous crustal thinning event, which culminated in displacement between the Iberian and European plates (Puigdefàbregas & P. Souquet 1986; Vergés & Garcia-Senz 2001). Continental rifting in the Pyrenean domain occurred in response to the counterclockwise rotation of Iberia relative to Europe, coeval with the onset of oceanic spreading in the Bay of Biscay between Chron M0 and A33o (approximately 125-83 Ma) (Le Pichon et al. 1970; Choukroune & Mattauer 1978; Olivet 1996; Gong et al. 2008; Jammes et al. 2009). About forty metric- to kilometer-sized fragments of subcontinental mantle rocks are found along the northern flank of the Pyrenees, in the North Pyrenean Zone (NPZ). They reside within or next to numerous lozenge-shaped basins flanking the North Pyrenean Fault (NPF). These basins are interpreted as the remnants of isolated, pull-apart or transtensive half graben basins formed in response to the eastward drift of Iberia along the NPF and later inverted during the Late Cretaceous-Early Cenozoic

127 Pyrenean orogeny (Le Pichon et al. 1970; Choukroune & Mattauer 1978). A typical flysch
128 sedimentation started during the mid-Albian within these basins (black flysch), which later
129 enlarged during the Late Albian and connected into one single, wider basin trough during the
130 Cenomanian (Debroas 1976; P. Souquet et al. 1985; Debroas 1990).

131 Various scenarios have been proposed for the emplacement of the ultramafic bodies, ranging
132 from purely tectonic mechanisms, such as solid intrusion of hot or cold mantle rocks into
133 sediments during strike-slip events (Avé-Lallemand 1967; Minnigh et al. 1980; Vielzeuf &
134 Kornprobst 1984), to tectono-sedimentary processes in which mantle rocks were exhumed
135 during Variscan time (Mattauer & Choukroune 1974; Fortane et al. 1986) and reworked in a
136 mid-Cretaceous wild flysch (Fortane et al. 1986). In recent re-examinations, various authors
137 propose that some of these bodies are fragments of sub-continental mantle basement partially
138 exhumed during Albian-Cenomanian times (Lagabriele & Bodinier, 2008; Jammes et al.
139 2009; Lagabriele et al. 2010; Debroas et al. 2010; Clerc et al. 2012). Within the NPZ, the
140 metasediments are locally strongly deformed and underwent a High Temperature - Low
141 Pressure (HT-LP) mid-Cretaceous metamorphic event, which lasted nearly 30 Ma from 110
142 Ma to 80 Ma (Azambre & Rossy 1976; Albarède & Michard-Vitrac 1978b; Montigny et al.
143 1986; Golberg et al. 1986; Goldberg & Maluski 1988; Thiébaud et al. 1988; Thiébaud et al.
144 1992). This metamorphism is considered as a consequence of crustal thinning (Golberg &
145 Leyreloup 1990) and developed in relation with hydrothermal circulations (Dauteuil & Ricou
146 1989). Hydrothermal circulations are also responsible for extensive albitization of some of the
147 North Pyrenean Massifs (Demange et al. 1999; Boulvais et al. 2007; Poujol et al. 2010), and
148 formation of massive talc deposits (Moine et al. 1989; Schärer et al. 1999; Boulvais et al.
149 2006) probably in relation to the activity of major ductile extensive shear-zones (Passchier
150 1984; St Blanquat et al. 1986; Costa & Maluski 1988; St Blanquat et al. 1990; St Blanquat
151 1993).

152

153 **III. Geology of the sampling sites**

154 The ophicalcites and related ultramafic breccias selected for the oxygen and carbon isotope
155 study were sampled from peridotite bodies exposed all along the NPZ (fig. 1). We selected
156 nine localities which are representative of the variety of the Pyrenean peridotites, and
157 presumably of the different geological processes involved in their exhumation history. Two
158 sampling sites are located in the western Pyrenees (Urdach and Tos de la Coustette), one in
159 the central Pyrenees (Moncaup) and nine in the Eastern Pyrenees (Ercé-Angladure, Lherz,
160 Fontête Rouge, Freychinède, Berqué, Vicdessos, Urs, Bestiac, Caussou).

161

162 **III.1. Western peridotites**

163 Several peridotite bodies outcrop in the Chaînons Béarnais, within the fold and thrust belt
164 Mesozoic sequence of the NPZ, at a longitude corresponding to the western termination of the
165 Paleozoic Pyrenean axial zone. The base of the stratigraphic sequence, exposed along the
166 Mail Arrouy, Sarrance and Layens post-Cenomanian thrusts (Casteras 1970), is composed of
167 Late Triassic evaporites, breccias and ophites overlain by Mesozoic platform carbonates
168 forming the original cover of the northern Iberian margin (Canérot et al. 1978; Canérot &
169 Delavaux 1986). In contrast to the Eastern NPZ, evidence of HT-LP metamorphism is
170 restricted here to some scarce and narrow regions bordering fault contacts with Triassic and
171 mantle rocks (Fortane et al. 1986; Thiébaud et al. 1992; Lagabrielle et al. 2010) and the
172 temperatures during peak metamorphism barely exceeded 400°C (Clerc 2012). Petrological
173 and geothermobarometric studies of the western ultramafic bodies show that they underwent a
174 two step exhumation with a first rise from 60 km to 25 km depth (1050-950°C), probably
175 during late Hercynian times, followed by a further step from 25 km to a shallower and cooler

(600°C) level (Fabriès et al., 1998). This second step is marked by the development of a mylonitic fabric, from 117 Ma to 109 Ma (Vissers et al. 1997; Fabriès et al. 1998).

The Urdach body is a 1.5 km wide peridotite slice exposed at the western termination of the Mail Arrouy thrust (fig. 2A). It is overlain by Paleozoic basement slices and surrounded on its western and southern sides by a large volume of unsorted sedimentary breccias and olistoliths composed of peridotite fragments associated with Paleozoic basement clasts from upper, middle and lower crustal levels. These debris are intermingled in the Cenomanian black flysch (Casteras 1970; Vielzeuf 1984; Souquet et al. 1985; Jammes et al. 2009; Debroas et al. 2010). Some authors considered that the Urdach body itself might be an olistolith settled in Cenomanian sediments (Duée et al. 1984; Fortane et al. 1986). Peridotite hydrothermal alteration led to pervasive serpentinization reaching 80%. This is a dominant character of the Urdach body (Fabriès et al. 1998).

The 400 m long Tos de la Coustette ultramafic body is located 3 km west of the Sarailé summit, at the western termination of the Sarrance anticline (fig 2a). Apart from the peridotites, the faulted heart of the Sarrance anticline includes, Paleozoic basement rocks and ophite lenses embedded within cataclastic Triassic sediments. It is thrust over the verticalized Urgonian limestones and Albian flysch of the Lourdios Syncline (Casteras 1970; Lagabrielle et al., 2010). The Tos de la Coustette body itself is in tectonic contact with small lenses of Paleozoic crustal rocks and Triassic metaevaporites outcropping both above and beneath the peridotites. Like the Sarailé peridotites, the environment of the Tos de la Coustette body is devoid of sedimentary breccias; instead these bodies are entirely surrounded by cataclastic breccias limited by tectonic contacts and are thought never to have been exposed to the seafloor (Canérot & Delavaux 1986; Lagabrielle et al. 2010).

III.2. Central peridotites

The Moncaup ultramafic body is part of a group of peridotites exposures lying around the Milhas massif, in the central Pyrenees (fig. 1). They are associated with basement rocks, variably brecciated Triassic sediments, ophites and Albian mafic intrusions. They are overlain in tectonic contact by highly metamorphosed Mesozoic marbles (Debeaux & Thiébaud 1958; Hervouët et al. 1987; Barrère et al. 1984). Although the peridotites have risen to near surface levels, there is no evidence for sedimentary reworking indicating their exhumation on the basin floor. Indeed, based on their geological setting, it can be deduced that the mantle rocks have remained capped by the Mesozoic marbles together with small slices of continental crust, during their uplift along the detachment fault (Lagabrielle et al. 2010).

III.3. Eastern peridotites:

The eastern Pyrenean peridotites are found within narrow belts of Mesozoic sediments of the NPZ, mainly limestones, pinched between the Axial Zone to the south and blocks of Paleozoic crust to the North representing the continental basement of the NPZ (North Pyrenean massifs) (fig. 1). Although the eastern Pyrenean mantle outcrops are often small and disconnected from an original substratum, one can still observe, on a decametric scale, a progressive transition from carbonate-free massive peridotites to high carbonate content breccias with all intermediates. On the rim of the ultramafic bodies, the massive peridotites are often crosscut by millimetric to centimetric calcite veins over the first few meters. In addition, in many localities, the peridotites are reworked within sedimentary polymictic breccias together with highly variable proportions of carbonate clasts. The amount of matrix of these breccias increases toward the carbonated end-member.

Most of the ultramafic bodies sampled for this study, from West to East, namely Ercé-
Angladure, Lherz, Fontête Rouge, Freychinède, Berqué, Videssos, Urs, Bestiac and Caussou,
display geological settings consistent with an origin as olistoliths surrounded by polymictic
detritic formation (fig. 2B, 3). They are interpreted as sedimentary records of the exhumation
of the peridotites on the floor of the Cretaceous basins (Lagabrielle & Bodinier 2008; Clerc et
al. 2012). The ultramafic-bearing breccias show sedimentary features such as grain-sorting
and crossbeddings and can be found away from the main bodies, indicating that they have
been transported by sedimentary processes. Lagabrielle & Bodinier (2008) showed that the
polymictic ultramafic-carbonate clastic sediments have been emplaced into fissures opened
within the exhumed massive peridotites, in a way similar to OC2 sedimentary ophiolites of
Lemoine et al. (1987). Similar features are reported in more detail, together with the presence
of ultramafic-rich debris flows and evidence of ultramafic rock-fall in the vicinity of the
Lherz body by Clerc et al. (2012). The peridotites show little serpentinization, developed
mainly along discrete, localized joints and fissures. The carbonates reworked in the detritic
formations surrounding the peridotites are strongly deformed and underwent HT-LP
metamorphism with peak temperatures commonly as high as 600°C (Golberg & Leyreloup,
1990; Clerc 2012). By contrast to the western peridotites, the eastern ones underwent a single
and rapid uplift event, which probably limited hydrothermal alteration and serpentinization
(Albarède & Michard-Vitrac 1978a; Fabriès et al. 1991; Henry et al. 1998).

IV. Description of the analyzed samples

IV.1. Sampling strategy and collected samples

The sampling strategy was to collect samples from the four main geological environments
identified and distinguished as follows: (1) poorly serpentinized peridotites surrounded by hot

metasediments (Eastern and central peridotites) either exhumed to the basin floor (Lherz, Bestiac, Caussou, Vicdessos, Urs, Ercé-Angladure) or only unroofed but never exhumed (Moncaup), and (2) highly serpentinized peridotites surrounded by cooler sediments (Western peridotites) either exhumed to the basin floor (Urdach) or only unroofed but never exhumed (Tos de la Coustette). The list of the 48 studied samples is given in Table 1. We focused this study on the Lherz and Urdach bodies since they are among the largest mantle outcrops in the Pyrenees and because they represent two well-studied end-members in terms of their geological environment. Furthermore, these two localities offer better outcrop conditions compared with the smaller bodies poorly exposed in areas presenting important vegetal covering and rock alteration.

IV.2. Field and macroscopic aspects:

IV.2.a. Western Pyrenean Ophicalcites:

The western ophicalcites appear essentially as veins of calcite infilling fissures and fractures opened within the ultramafic rocks. The fractures present relatively constant and repeated orientations (fig. 4A). Particularly well observable in a quarry opened on the western side of the Urdach lherzolite body, they were first described by Monchoux (1970) and later interpreted as typical ophicalcite textures by Jammes et al. (2009). These authors highlighted their similarities with structures observed within exhumed mantle in the Alps and drilled off Iberia (Manatschal 2004). They consist mainly in millimetric to decimetric veins of clear white calcite (fig. 4B). The thickest veins are actually constituted of an accumulation of numerous veins and veinlets separated by thin fragments of peridotite strapped from the rims.

At Tos de la Coustette, the ophicalcites also appear as a dense mesh of very fine veinlets and as a pervasive substitution of serpentine minerals by patches of carbonate, barely visible on a

macroscopic scale, invading highly serpentized peridotites (fig. 4C and D). Similar textures have also been described further east in the Avezac-Moncaut peridotites (Fabriès et al. 1998).

IV.2.b. Central Pyrenean Ophicalcites:

At least two types of ophicalcites were identified in the Moncaup peridotites. The first one, observed close to the damage zone of the tectonic contact between the peridotites and the overlying marbles, is represented by millimetric veins of coarse translucent sparite (fig. 4E). The veins crosscut and hence post-date a mylonitic fabric affecting the peridotites. The second one, observed in the damage zone of the detachment fault, consists of light brown micro-conglomerates and micrite infilling veins and cavities opened in the altered and dislocated peridotites (fig. 4F). The cavities present contorted and rounded rims. The micro-sediments show complex multi-generation evolutions with successive stages of deposition indicated by several color shades and crosscutting sparitic veins. The micro-conglomerates are laminated and present clear grain-sorting.

IV.2.c. Eastern Pyrenean Ophicalcites:

In the Eastern Pyrenees, ophicalcites and polymictic ultramafic-marble bearing breccias are observed within, close to, and even far away from the main peridotite bodies. Most of the clasts are composed either of ultra-fresh subcontinental peridotites or of marbles bearing mineral assemblages typical of the HT-LP mid-Cretaceous metamorphism. They are associated with a minor proportion of fragments deriving from gabbros, Triassic ophites Mesozoic meta-pelites and meta-evaporites and Paleozoic basement rocks (Lagabrielle & Bodinier 2008; Clerc et al. 2012).

In the Etang de Lherz area, Lagabrielle and Bodinier (1998) identified four main types of breccias and ophicalcites that can be extended to the other peridotite outcrops of the Eastern Pyrenees. (i) Type 1 is found in direct contact with or within the ultramafic body, it consists

294 of a carapace of monomictic breccias resulting from the cataclastic deformation of the
295 peridotites during exhumation. These breccias typically lack carbonate clasts and contain little
296 to no carbonate veins and cement. Therefore, they will not be considered further in this study.

297 (ii) Type 2 breccias, generally found in close contact with type 1 breccias, are ultramafic-
298 dominated polymictic breccias resulting from the sedimentary reworking of type 1. (iii) Type
299 3 breccias consist of thin layers of graded ultramafic litharenites bearing isolated cm-sized
300 clasts of peridotites and marbles and presenting slumps and syn-sedimentary normal faults
301 (fig. 5A and B). Within the type 3 breccias, the peridotite clasts display many different
302 lithologies (lherzolite, harzburgite, websterite, pyroxenite etc.), variable mantle textures
303 (equant coarse-granular to mylonitic) and variable degrees of serpentinization (totally fresh to
304 fully serpentinized, fig. 5C and D). These observations point to mixing and transport from a
305 relatively distant source by sedimentary processes. Furthermore, clasts of former monomictic
306 carbonate breccias and polymictic UM-marble breccia are also reworked in these formations,
307 pointing to their late deposition with regard to the exhumation history (Clerc et al., 2012). (iv)
308 Type 4 breccias correspond to clastic rocks closely resembling the OC2 sedimentary
309 opicalcites of Lemoine et al. (1987). Clear white calcite veins penetrate fractured ultramafic
310 blocks in which they separate angular fragments. There is a striking association of these veins
311 with matrix-supported microbreccias similar to those forming the matrix of the type 2 breccias
312 (fig. 5E). The veins are smoothly rooted in the matrix and seem to be its extension in narrow
313 domains where the clasts were too big to fit. However, some veins crosscut pre-existing
314 matrices, pointing to a contemporaneous formation of matrices and veins during
315 sedimentation accompanied by multi-stage circulations of cementing fluids. In some outcrops,
316 the ultramafic clasts exhibit a centimeter thick orange-brown oxidation ring on their contact
317 with carbonate matrices and veins (fig. 5 E and F). This feature is also commonly observed in
318 oceanic opicalcites (Boschi et al. 2006; Dick et al. 2008). This oxidation pattern does not

appear on the rims of the thinnest veins.

Ophicalcites at the Bestiac locality show similar features and offer exceptional conditions to investigate the successive generations of serpentinization and carbonation. The peridotite consists of tens of lens-shaped bodies less than a few hundred meters in size and embedded in a metamorphic bimodal ultramafic-marble breccia. Angular to slightly rounded centimeter-sized clasts of lherzolite are found more than 500 m away from the main blocks, a pattern clearly not consistent with any fault-assisted mode of emplacement. A few outstanding outcrops are visible in several abandoned caves and galleries dug for prospection of asbestos. Fresh to dark green serpentinites are crosscut by networks of cm-thick light green fibrous serpentine (likely chrysotile) delimitating metric lumps which mimick at a meter-scale the classical microscopic mesh-texture of serpentinized peridotites (Wicks & Whittaker 1977) (fig. 5G). The serpentine veins commonly show oblique sigmoidal fibers indicating shearing contemporaneous to brittle deformation responsible for vein development. Pluri-millimetric veins of calcite crosscut through this latest generation of serpentine veins that acted as a weak gateway for sediments and fluids during the ultimate stage of deformation and sedimentary reworking (fig. 5H). Some of the calcitic veins have a reddish coloration and increased concentration of oxides, suggesting possible syn- or post-diagenetic hydrothermal circulation. As in the Lherz area, these remarkable ultramafic-bearing formations have a relatively restricted extension and appear within large volumes of clastic formations devoid of any ultramafic component.

IV.3. Microscopic description:

Ophicalcite from the Urdach ultramafic body have millimetric veins of sparite. Several vein generations crosscut each other with varying angles. The calcite veins commonly show crack-

343 seal aspects. Symmetric layers of calcite with varying intensity in transmitted light and
344 cathodoluminescence (CL), induced by minor variations of composition or inclusion
345 concentration, are separated by a central suture (fig. 6A). Some of the largest veins actually
346 consist of an accumulation of numerous sub-parallel veinlets, less than a micrometer wide,
347 invading the serpentinite (fig. 6B). Finally, some other veins show zoned botryoids of
348 fibrous radiating calcite (fig. 6C)

349 In the Tos de la Coustette opicalcites, the carbonates mainly appear as micrometric to
350 millimetric patches of calcite extensively dispersed within the serpentinite (fig. 6D). Intimate
351 repartition of calcite and serpentine indicate a pervasive calcification by replacement of some
352 serpentinous phases. The poorly elongated calcite aggregates develop following a general
353 foliation marked by magnetite alignments and thin yellow serpentine veinlets. Surface
354 estimate by digital image treatment indicates that the rock includes up to 55 % calcite, 40 %
355 serpentine and 5 % magnetite with minor phases.

356 The matrix of the eastern Pyrenean opicalcites and associated polymictic breccias consists of
357 a pale-orange litharenite composed of infra-millimeter-sized angular clasts of marbles mixed
358 with varyingly serpentinized ultramafic clasts and isolated minerals (pyroxenes, olivine, green
359 and brown spinels). This litharenite sometimes appears laminated and shows graded-bedding
360 due to sedimentary transport (Lagabriele & Bodinier 2008; Clerc et al. 2012) (fig. 6E). In
361 contrast to the veins, the matrices of the breccias, show much less evidence for
362 recrystallization: there are, for example, a few newly formed metamorphic phyllosilicates and
363 amphiboles.

364 Most of the veins observed in the Eastern Pyrenean opicalcites consist of clear and equant
365 sparry calcites (fig. 6F). The veins cross cut alternatively the ultramafic clasts and the matrix
366 of the breccias in which they often seem to be rooted. In the simplest cases, a single

generation of calcite crystal nucleates from the rims of the veins and grows toward the center where it joins in a central suture. In some cases, the growth resumed or the fracture was reopened, leading to the formation of vugs. Most of the veins show multistep histories with successive infillings of sparite particularly well highlighted by varying luminescence in CL (fig. 6G). When pure enough, the veins are clearly recrystallized as evidenced by the conservation of former zoned calcite dogteeth ghosts within bigger equant neoformed crystals. The borders of the neoformed crystals are independent from those of the ghosts that they overprint (fig. 6H). When thick enough, the veins are generally filled with detrital material including micro-fragments of serpentine, oxides and calcite clasts mixed within a micrite. Although they lack microfossils, such veins resemble the neptunian dykes and veins formed on the subaquatic floor and consequently opened to sedimentary influx (Smart et al. 1987; Laznicka 1988; Winterer et al. 1991).

V. Methods for determination of O and C isotope compositions

Rock samples were sawed to select well-oriented and relevant planes. The sawed faces were cleaned using water and pulsed with dry air before micro-drilling. A minimum of about 20 mg of powder was collected for each sampling site.

The O and C isotope compositions were measured using a VG SIRA 10 triple collector mass spectrometer at the University of Rennes 1, on the CO₂ released during reaction of calcite with anhydrous H₃PO₄ in sealed vessels at 50°C (McCrea 1950). NBS 19 and internal-lab standard references materials (Prolabo Rennes) were continuously measured during the course of this work. NBS 19 measured values were $\delta^{18}\text{O} = 28.26 \pm 0.09$ (1 σ , n=12) ‰ and $\delta^{13}\text{C} = 1.86 \pm 0.02$ (1 σ , n=12) ‰. Results were corrected in accordance with the NBS 19 recommended values of 28.65‰ and 1.95‰, for O and C respectively. The analytical uncertainty is estimated at 0.15‰ and 0.1‰ for O and C.

VI. Results

The isotope compositions for the 48 analyzed samples are presented in table 1 and figure 7. The calcite phase found in clasts, veins and matrices from the Pyrenean ophicalcites and ultramafic-bearing breccias displays a wide range of oxygen isotope compositions with minimum values of 12.6 and 13.8‰ (vs. SMOW) measured in Moncaup and Tos de la Coustette veins (Western ophicalcites), and maximum values of 25.1‰ in the matrices of samples from Etang de Lherz area (fig. 4 & 6; Eastern ophicalcites). The carbon isotope compositions range from -5.8‰ (vs. PDB) in Moncaup samples to 1.5‰ in Lherz samples (matrices). As a whole, the field of isotopic compositions of Pyrenean ophicalcites is displaced from the one of the Iberian margin ophicalcites by lower $\delta^{18}\text{O}$ values and slightly lower $\delta^{13}\text{C}$ values (arrow in figure 7). Whereas no clear distinction can be made when comparing Pyrenean ophicalcites with Alpine and Apenninic ones, it seems that hydrothermal ophicalcite worldwide compare well with ophicalcites from the Western Pyrenees. First order analysis of the distribution of the oxygen and carbon isotope compositions implies to distinguish two separate domains: i) Ophicalcites from the Urdach and Tos de la Coustette ultramafic bodies have rather low and variable values of $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$, ranging from $\delta^{18}\text{O} = 13.8$ to 22.1 ‰ and $\delta^{13}\text{C} = -5.22$ to 1.12 ‰ and scattered around a mean value of $\delta^{18}\text{O} = 19.1$ ‰ and $\delta^{13}\text{C} = -1.0$ ‰. Ophicalcites from Tos de la Coustette body plot into a distinct field having an extremely low value of $\delta^{18}\text{O}$. ii) Ophicalcites from the Eastern Pyrenean bodies display low dispersion (21.3 to 25.1 ‰) in $\delta^{18}\text{O}$ but variable $\delta^{13}\text{C}$ values (1.53 to -2.47 ‰). Among the Eastern Pyrenean ophicalcites, very poor discrimination can be made based on the composition of veins and matrices since both display almost similar values with mean $\delta^{18}\text{O}$ of 23.4 ‰ in the veins and 24.1 ‰ in the matrices. The O and C isotope compositions of the nine samples containing both veins and matrices are reported in figure 8. One can observe good correlations between the compositions of matrices and veins with the exception of samples

LHZ8 and LHZ64 whose veins are significantly depleted in ^{18}O and slightly enriched in ^{13}C . We note that the pluri-millimetric size of our sampling drilling spots provide bulk estimates of the isotopic compositions of the veins and matrix but do not allow the complex multistage history recorded in some of the veins to be deciphered (i.e. fig. 6G). The isotope composition of the matrices does not correlate with the variable lithology of the clasts (either ultramafic and/or carbonate), nor with the relative amount of clasts. In contrast the isotopic compositions of the marble clasts are highly variable and plot within a larger field than the matrices and veins (Fig. 7). Also, there is no correlation between the isotopic compositions of clasts and the veins or matrices that host them. Actually, these clasts underwent a strong HT/LP metamorphism and may contain abundant silicates (phyllosilicates, amphiboles, scapolite). Closed-system isotopic equilibration between the carbonate and the silicate phases likely introduced variable isotopic alteration of the carbonate phase, depending on the initial amount of detrital silicates in the sedimentary precursor (see for example Valley, 1986; Boulvais et al., 2000). Also, open-system alteration during syn-metamorphic infiltration possibly caused isotopic shifts, which remain difficult to estimate here because we have no more information on the initial geometry of the clast (for example the distance to a lithological discontinuity). The ophicalcites from the Moncaup body display two distinct generations of carbonates with distinct isotopic compositions (fig. 4C and D). Such differences in isotopic compositions are consistent with the occurrence of two types of textures as described in section IV.

VII. Discussion

VII.1. Origin of the various types of ophicalcites

Based on the petrographic descriptions on the one hand and on the stable isotope compositions on the other, we are able to distinguish three main categories of ophicalcites associated with the subcontinental mantle bodies of the northern Pyrenees (table 2).

The first type of ophicalcites or *hydrothermal type*, as defined in the Tos de la Coustette body results from peridotite carbonation by veins and pervasive substitution of the serpentinite minerals by low $\delta^{18}\text{O}$ calcite. The low $\delta^{18}\text{O}$ values of calcite indicate that carbonation occurred from rather hot fluids. Comparable $\delta^{18}\text{O}$ values have been measured in ophicalcites formed in oceanic and ophiolitic hydrothermal systems (Lavoie & Cousineau 1995; Artemyev & Zaykov 2010). Due to its low $\delta^{18}\text{O}$, the first generation of coarse crystalline calcite veins described in the Moncaup peridotite likely corresponds to this type of hydrothermal ophicalcite. The difference in texture types between the Moncaup and the Tos de la Coustette ophicalcites may be explained by the very different rheology and chemical response to fluid circulation of the unserpentinized peridotite at Moncaup compared with the totally serpentinized peridotite of Tos de la Coustette.

The second type of ophicalcites or *tectonically-controlled type* is well characterized in the Urdach body. It consists of massive serpentinized peridotites, indifferently lherzolite or harzburgite, crosscut by successive generations of millimetric to centimetric calcite veins with intermediate isotopic compositions. The tectonic control of calcite crystallization is documented by the distribution of veins along preferential planes and their crack-seal geometry. Such calcite crystallizations likely record the arrival of the peridotite close to seafloor environments, directly under the influence of waters with intermediate temperature. Different generations of veins cross-cutting each other with slight variations in isotopic composition may reflect some temperature variations during the successive steps of fracturing / precipitation. In sample URD 1, a first generation of vein with a lower $\delta^{18}\text{O}$ values ($\delta^{18}\text{O}=18.6\text{‰}$) is cut by a later generation with a higher $\delta^{18}\text{O}$ value ($\delta^{18}\text{O}=21.1\text{‰}$). This is

consistent with cooling during vein formations, in consequence of progressive exhumation, provided that the isotopic composition of the invading fluid, and then its source, remained constant throughout the history of this sample.

The third type of ophicalcites, dominant in the eastern Pyrenees, is *sedimentary ophicalcite*. It consists of a cogenetic association of calcite vein and polymictic breccias. The matrix-supported to clast-supported polymictic breccias are composed of variable proportions of marbles and UM clastic material. Polymictic compositions and typical sedimentary features such as grain-sorting and cross bedding indicate that these ophicalcites have a sedimentary origin (Clerc et al., 2012). Their wide lithological variety, both in UM and metasedimentary material, likely results from sedimentary transport and mixing. By analogy with neptunian veins observed in other extensional settings (Winterer et al. 1991), the micrite-filled brittle fractures have been interpreted as very late, near surface fracturing of the exposed ultramafic basement (Lagabriele & Auzende 1982; Morgan & Milliken 1996), possibly leading to gravitational instabilities: slumping, slope failure, and landslides as described at ODP site 899 by Gibson et al. (1996). The sparite-filled veins and veinlets, either reworked in the breccias, smoothly rooted in the matrix or crosscutting clasts and matrix reveal a multistage deposition history, already implied by the presence of breccias clasts reworked in the breccias (Clerc et al. 2012). Bernoulli & Weissert (1985) describe similar cogenetic and simultaneous sediment infillings and calcitic cement precipitation in Alpine ophicalcites. Such fractures must have allowed the circulation of sedimentary fluids or early diagenetic fluids in domains where restricted dimension hindered the penetration of sedimentary material. The isotopic compositions of matrices and veins (Fig. 8) show a good correlation in both the oxygen and carbon systems, which confirm the idea that both features developed from the same reservoir. Since the relationship is valuable on a rather large range of $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$, one can infer that

the system of vein + matrix development was not connected to an external reservoir which would have produced veins with distinct compositions from the ones of the matrices.

Precipitation of acicular aragonite has commonly been correlated with warm water temperatures, high Mg/Ca ratios, high salinity, and high carbonate concentrations, conditions reached in the uppermost levels of serpentine seamounts (Haggerty 1987; Lagabriele et al. 1992). Similar thermal and chemical conditions are associated with fibrous, botryoidal calcite occurrences (Folk 1974; Surour & Arafa 1997), and botryoidal calcite could also represent a replacement texture of acicular radiating aragonite (Ross 1991). More equant and bladed sparry calcite has been correlated with cooler, deeper marine or meteoric settings, typically with low Mg, and carbonate concentrations (Folk 1974; Burton & Walter 1987). Instead, geochemical data (trace element and isotopic signatures) from Iberian margin ophicalcites indicate a seawater imprint at temperatures of 10-20°C, consistent with an early Cretaceous seawater only slightly modified by interaction with serpentinized peridotite basement (Milliken & Morgan 1996). For that reason, Morgan & Milliken (1996) suggested that the temporal evolution in the carbonate phase and morphology, from precipitation of aragonite, followed by fibrous, botryoidal calcite and finally to coarse, bladed sparry calcite may be controlled primarily by fluid flow rates through the vein rather than by variations of the chemical and thermal parameters (fig. 9).

The low temperature ophicalcites from the Moncaup body (MP84a, b, c) are peculiar in that they have extremely low $\delta^{13}\text{C}$ (< -5.00 ‰), indicative of interaction with organic material. Such carbon isotope compositions are commonly observed in karstic or calcrete precipitations from continental/meteoric waters transiting through soils and vegetation. These peculiar ophicalcites are located immediately below the cataclastic formations staking out the detachment fault between the peridotites and the overlying marbles. Due to the solubility and permeability contrast between these two formations, this interface is prone to concentrating

groundwater. However, we cannot specify if the formations observed are contemporaneous of any very early exhumation of the mantle rocks to subaerial (onland) environments in the Cretaceous or if they result from a later karstification and/or replacement of pre-existing ophicalcarbonates. Regardless the exact explanation, these values strongly differ from the rest of our dataset by a clear shift toward lower $\delta^{13}\text{C}$ values, allowing the distinction to be made between a surface-derived cement precipitated in karstic environments and sedimentary ophicalcites deposited in subaqueous conditions.

VII.2. Environmental conditions for the formation of Central and Eastern Pyrenean ophicalcites

The isotopic compositions of the Pyrenean ophicalcites fall into the same field as other ophicalcites from the literature (fig. 7). Only the three samples from Moncaup MP84a, b, and c are out of this range because of their low carbon composition indicative of interactions with carbon from soils, as discussed above. Ophicalcites from the Alps and Apennine were interpreted as having been formed by interaction with seawater moderately heated to 80 to less than 200°C (Barbieri et al. 1979; Barrett & Friedrichsen 1989; Früh-Green et al. 1990; Schwarzenbach 2011) or by sedimentary fluids later re-equilibrated during Alpine metamorphism (Weissert & Bernoulli 1984; Barbieri et al. 1979).

Samples from the Eastern Pyrenees are clearly recognized as sedimentary ophicalcites by their textures. Consistently, the Eastern Pyrenean ophicalcites have the highest $\delta^{18}\text{O}$ values measured in our sample set, a feature which is indicative of low temperatures of precipitation at near surface conditions. However, we notice a major difference in the oxygen isotope composition with ophicalcites from the Iberian margin (Agrinier et al. 1988; Evans & Baltuck 1988; Agrinier et al. 1996; Milliken & Morgan 1996; Plas 1997; Skelton & Valley 2000). Indeed, in the Iberian ophicalcites, which precipitated from low temperature seawater, the

536 $\delta^{18}\text{O}$ values of calcite are around 31‰ with $\delta^{13}\text{C}$ values varying between -1.7 and 2.2‰.
537 Instead, the Eastern Pyrenean sedimentary opicalcites analyzed in our study have
538 significantly lower $\delta^{18}\text{O}$ values (around 24‰) with carbon isotope compositions ranging from
539 -2.5 to 1.4‰, so that even if the envelope of Pyrenean sedimentary opicalcites mimic the
540 Iberian margin ones, it is displaced in the $\delta^{13}\text{C}$ vs. $\delta^{18}\text{O}$ space (grey arrow, fig. 7). At least,
541 three hypotheses can be proposed in order to explain these differences (fig. 10).

542 1. Lowering of the O and C isotope compositions could result from a metamorphic imprint
543 with introduction of externally-derived fluids. Isotopic exchanges between neoformed calcites
544 and the mineral silicates, mainly serpentinite, which form a significant portion of the detrital
545 material associated with the sedimentary opicalcites, may lower the O isotope composition
546 of the calcite. The breccias and opicalcites rework clasts of pre-rift material that already bear
547 signs of high-grade recrystallization during the regional HT/LP metamorphism, with the
548 development of scapolite and amphibole. The deposition of the breccias and opicalcites
549 hence occurs after the peak of metamorphism. But the long-lasting mid-cretaceous thermal
550 anomaly is followed by a lower grade metamorphism that affects the Turonian-Senonian post-
551 rift sediments, with a maximum temperature near 350°C (Ternet et al., 1997; Clerc 2012).
552 This later and lower grade metamorphism may hence have affected the opicalcites and
553 breccias presented in this study. However, the petrographical effect of metamorphism on
554 these rocks seems rather limited since the matrices show only little recrystallization.
555 Furthermore, we would expect that the oxygen isotope composition would be much more
556 variable depending on the fluid/rock ratio. This is the case for a metamorphic-driven
557 alteration of the isotopic signal as shown from the study of the Alpine opicalcites (Fig. 7;
558 Weissert & Bernoulli 1984; Früh-Green et al. 1990). Also, one would have expected that the
559 veins show more constant composition instead of displaying delta values that correlate with
560 the values of matrices (Fig. 8).

2. The low O and C compositions may be the result of a hot diagenesis from marine porewater during carbonation. This hypothesis, which implies active circulation of relatively hot fluids in the boundary layer between the ultramafic basement and seawater, is consistent with the high geothermal gradients known to characterize the basins of the North Pyrenean Zone during the Albian-Cenomanian period (Dauteuil & Ricou 1989; Golberg & Leyreloup 1990). The thermal gradients for the Albo-Cenomanian metamorphism can be higher than 100°C/km. In such conditions, we may also consider that unconsolidated sediments still soaked with seawater can be rapidly buried and heated to temperatures as high as 50-80°C. At such temperatures, the calcite precipitated from seawater ($\delta^{18}\text{O} = 0\text{‰}$) would have a $\delta^{18}\text{O}$ value of around 23‰ (considering the isotopic fractionation coefficient of Zheng, 2011), a value that compares well with the data of the Eastern ophicalcites. Thermal gradients as high as 160-180°C/km are known in present days, for instance in the Salton Sea geothermal field (Elders et al., 1972; Muffler & White, 1969). Comparable environments can also be found on the top of mantle exhumed in oceanic domains, where hydrothermal fields develop over areas several square kilometerswide (around 2.5km² at the Rainbow hydrothermal site, German et al., 1996; around 2km² at the Lost City hydrothermal site, Kelley et al., 2001, along the Mid-Atlantic Ridge). In similar settings, in the ophiolites of East Liguria, Spooner and Fyfe (1973) describe temperatures as high as 400°C for shallow depth of circa 300 m below the water/rock interface.

3. As a last hypothesis, it may be that the Eastern Pyrenean sedimentary ophicalcites formed in a low-temperature but endorheic environment, dominated by continental waters and possibly disconnected from the ocean. Indeed, the oxygen composition measured here is about 7‰ lower than the present-day marine Iberian ophicalcites, a difference consistent with the difference between marine and unspecific waters with a continental affinity. Note first that a continental environment is not precluded by the existence of marine fauna, which would

have been observed in sediments associated with opicalcites. The hypothesis of an endorheic environment dominated by continental waters has to be questioned with respect to the paleogeographic reconstructions of the Pyrenean realm during mid-Cretaceous times. These reconstructions point to the existence of a V-shape opening oceanic domain, narrowing from the Bay of Biscay toward the East where it propagates into the continental crust (Jammes et al. 2009 and references therein). The opening of numerous transtensive basins of limited extension in the central and eastern part of the pre-Pyrenean domain may have been such that these basins were endorheic (Le Pichon et al. 1970; Choukroune & Mattauer 1978), partially disconnected from a marine influence at the time of opicalcite development. This hypothesis is consistent with the stratigraphy of the Albian sediments deposited in disconnected basins separated by positive reliefs (Debroas, 1976, 1990; Souquet et al., 1985). Some of these reliefs such as the future North Pyrenean massifs and the future Axial Zone were emerged, as shown by the outline of the Cenomanian transgression and by evidence of cooling and sedimentary reworking of crustal material (Filleaudeau et al., 2011). Such short wave-length and high amplitude morphology likely resulted from the flexural response of the lithosphere to the extreme crustal stretching due to the extensional Albian-Cenomanian tectonics along the Pyrenean realm. In such conditions, we may envision that the area where mantle has been exhumed was surrounded by subaerial catchments and, at that time possibly disconnected from the sea. A possible present-day analog is represented by the Salton Sea basin, which is an endorheic continental basin located ahead of the propagating oceanic spreading axis of the Gulf of California. Circulations of continental waters within sediments are also described in more opened environments, for example at the foot of the Aden Gulf margins (Lucazeau et al. 2010).

At this time, it is difficult to select between the three hypotheses even if the last one is the simplest in term of the isotopic composition record. Additional informations like fluid

inclusion data is needed to strengthen this hypothesis. It remains clear that, regardless of the exact explanation, sedimentary opicalcites in the Eastern Pyrenees are distinguishable from those in the Central and in the Western Pyrenees.

VII.3. Western and Eastern Pyrenean opicalcites: why are they so different?

The three types of opicalcites identified in this study have to be considered within the frame of the exhumation history of the Pyrenean peridotites presented in section III a and c and as summarized in figure 11. We highlight a clear distinction between the Eastern and Western Pyrenean isotope composition of opicalcites also evidenced by the different degrees of serpentinization of the mantle that host them, by the temperatures of the metamorphic peak in the surrounding metasediments (Choukroune & Seguret, 1973; Golberg & Leyreloup, 1990; Ravier, 1959; Clerc 2012) and by the typologies of opicalcites (fig. 11). Following our observations, and in accordance with phase stability of serpentine mineral (Andreani et al. 2007), it appears that the variable serpentinization degree of the Pyrenean peridotites can be linked, primarily, to the thermal anomaly accompanying their exhumation. Since carbonation postdated serpentinization, the degree of serpentinization appears as a key factor influencing the development of opicalcites. Volume increase and rheological softening induced by serpentinization tend to favor the development of numerous fractures, allowing an endogenic precipitation of carbonates as observed in the Western opicalcites. In contrast, the less serpentinized peridotites exposed in Moncaup and in the Eastern Pyrenees must have had a different behavior during uprising to crustal levels. Their contrasting rheology with the surrounding rocks implies that they were probably still massive and competent until exhumation. This could explain the predominance of superficial opicalcites found in these localities. The fact that the Eastern Pyrenean peridotites remained preserved from hydrothermal circulation may explain their scarce serpentinization. In addition, such a lack of fluid activity may also be responsible for the preservation of high temperature mineral

assemblage since heat was evacuated by convection. The reason of the limited access of fluids to the exhuming peridotites is not yet understood. We could suggest either i) a blanketing effect of the Mesozoic sedimentary cover that would inhibit water infiltration, or ii) fast exhumation in a continental environment with limited amounts of water available for hydrothermal circulations.

Conclusion

On the basis of close fieldwork, petrographic and geochemical considerations, we present the first comprehensive review of the Pyrenean opicalcites. Our results, in accordance with published studies on worldwide occurrences of opicalcites allowed us to distinguish and characterize three main types of opicalcite (table 2): (i) hydrothermal opicalcites resulting in low $\delta^{18}\text{O}$ calcite (13.8‰) pervasively replacing serpentinite; (ii) intermediate or syn-tectonic opicalcites developed along with brittle discontinuities in the serpentinitized mantle rocks, with intermediate calcite isotope compositions ($\delta^{18}\text{O}$ around 20.0‰; $\delta^{13}\text{C}$ around -1.06‰); (iii) sedimentary opicalcites occurring as breccias and neptunian dykes, associated with the circulation of syn-sedimentary fluids. The isotopic compositions for this sedimentary type show the highest $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ values of the set, consistent with the cold temperatures of precipitation expected in a sedimentary environment. We note a non-linear distribution of the different opicalcite type along the Pyrenean range, with dominant endogenic ones in the West and dominant exogenic ones in the East. Such a distribution is clearly linked to a difference in serpentinitization degrees likely related to the different exhumation histories and subsequent variable thermal anomalies.

We further investigated the possible origins of the fluid and temperatures at which the calcite may have precipitated in both hydrothermal and sedimentary domains. We present three

660 possible explanations for the relatively low values of the sedimentary ophicalcites: i) a post-
661 sedimentary metamorphic imprint; ii) a hot diagenesis in relation to the high regional thermal
662 gradient; iii) sedimentation in an endorheic basin. This last hypothesis is consistent with the
663 paleogeographic reconstructions of isolated Albo-Cenomanian basins at the tip of a
664 propagating rift. Finally, we highlight a major difference between Eastern and Western
665 ophicalcites, linked primarily to the variable degree of serpentinization. Considering the
666 strong control of serpentinization on the rheology of mantle rocks we propose that the
667 formation of different ophicalcites types is controled by the degree of serpentinization,
668 depending itself on the rate and modalities of exhumation of the subcontinental mantle during
669 extreme crustal stretching.

Figure Caption

Figure 1. Simplified geological map of the Northern Pyrenean belt with location of the peridotite bodies sampled in this study.

Figure 2. A: Simplified geological map of the Urdach and Tos de la Coustette in the Mail Arrouy and Sarrance *Chaînon Béarnais* with sample sites. B: Simplified geologic map of the Aulus basin presenting the extent of exposure of the peridotite bearing deposits surrounding the *Etang de Lherz* area with the location of the Freychinède, Fontête Rouge, and Berqué samples sites.

Figure 3: Photograph of an ultramafic olistolith in the Aulus basin illustrating the progressive transition from polymictic breccias to massive peridotite penetrated by calcitic veins

Figure 4: Macroscopic aspects of some of the western Pyrenean ophicalcites. A and B: development of calcites veins along tectonic discontinuities in the Urdach peridotite body. C: Mesh texture in highly serpentinized peridotite of Tos de la Coustette. D: Pervasive carbonation and veins in Tos de la Coustette peridotite. Calcite veins (E) and cavities infillings (F) in the Moncaup ultramafic body.

Figure 5: Macroscopic aspects of some of the eastern Pyrenean ophicalcites. A: Bimodal litharenite presenting slumps and syn-sedimentary normal faults from Lherz. B: Grain sorting

1131 in polymictic litharenites from Lherz. C and D: Breccia reworking fresh (orange to green) and
1132 serpentinized (dark green to black) peridotites in a calcitic matrix from the Lherz ophicalcites.
1133 E: Close association of matrix and veins in a typical ophicalcite from Vicdessos. F: Exposure
1134 of an ultramafic body presenting a centimetric orange-brown oxidation ring on the contact
1135 between peridotites and carbonates (Ercé-Angladure) G: Metric-sized mesh texture in the
1136 Bestiac peridotites. H: Detail of F showing calcite veins cross-cutting the latest serpentinite
1137 veins.

1138

1139 Figure 6: Microscopic aspects of the Pyrenean ophicalcites. A: Seal crack calcite vein from
1140 Urdach in cathodoluminescence (CL) and redrawn. B: Micrometric veinlets from Urdach. C:
1141 Botryoidal calcite in a vein from Urdach, in transmitted light and CL. D: Replacement texture
1142 of the ophicalcites from Tos de la Coustette, polarized light. F: Clear sparry calcite in veins
1143 from Lherz. G: Close vein/matrix association in transmitted light and CL. H: Dogtooth calcite
1144 ghosts in recrystallized veins, in polarized light and Redrawn.

1145

1146 Figure 7: $\delta^{13}\text{C}$ vs. $\text{d}18\text{O}$ diagram showing the isotopic compositions of the Pyrenean
1147 ophicalcites (veins, matrices and clasts). Shaded areas represent values from the literature for
1148 ophicalcites from the Iberian margin and Galicia bank (Evans & Baltuck 1988; Milliken &
1149 Morgan 1996; Plas 1997; Skelton & Valley 2000); the Alps and Apennines (Brotzu et al.
1150 1973; Barbieri et al. 1979; Weissert & Bernoulli 1984; Barrett & Friedrichsen 1989; Demeny
1151 et al. 2007) and from other hydrothermal ophicalcites (Lavoie & Cousineau 1995; Artemyev
1152 & Zaykov 2010).

1153

1154 Figure 8: Comparison of the C and O isotope compositions of calcitic veins and matrices in
1155 the ophicalcites from Eastern Pyrenees.

1156

1157 Figure 9: Comparison of calcite microtextures in veins and matrices from this study and from
1158 the Iberian margin (Morgan & Milliken, 1996).

1159

1160 Figure 10: Cartoons illustrating the three possible mechanisms responsible the low O
1161 composition of the sedimentary ophicalcites from the Eastern Pyrenees.

1162

1163 Figure 11: Sketches presenting the exhumation history of the Eastern and Western Pyrenean
1164 peridotites in the light of our isotope study. Serpentinization processes are represented by
1165 green colors and the formation of ophicalcites by blue colors.
