Heavy precipitation events (HPEs) can be a major cause of damage and casualties in the Mediterranean basin. With the use of atmosphere-ocean coupled regional climate models (AORCMs) and the advantage of 24 years of simulation (1989-2012), we identified regions with potential impact of submonthly air-sea coupling on HPEs among the regions hit by heavy rain during HyMeX 1st special observation period (SOP1): Valencia in Spain, the Cévennes in Southern France, Liguria in Northwestern Italy, Calabria in Southern Italy and Northeastern Italy. A first evaluation of the two AORCMs (MORCE and CNRM-RCSM4) against gridded precipitation datasets showed that 70 to 90% of the 30 most intense HPEs simulated were observed HPEs for most regions. The Cévennes, Valencia and Calabria were the only three regions to show a statistical relationship between rain differences and SST differences where the low-level jets that feed the events most frequently blow. This sensitivity of precipitation to SST changes is due to low-level wind changes related with changes in surface heat fluxes. Based on the calculation of submonthly variations in these regions during HyMeX, HPEs on the 28/09/2012 and 12/10/2012 in Valencia and on 25-26/10/2012 in the Cévennes have most probably been affected by submonthly air-sea coupling.

Key Words: Heavy precipitation events, Mediterranean, air-sea coupling, atmosphereocean regional climate model

1. Introduction

The configuration of the Western Mediterranean basin is an arc of mountains, from southwest to northeast: the Atlas mountains, the Iberian and Betic chains in Spain, the Pyrenees, the Massif Central in France, the Alps, the Apennines in Italy and the Dinaric Alps in the Balkan peninsula (Fig. 1a) surrounding the Western Mediterranean basin. The coastal Atlas mountains, the Iberian and Betic chains, the Massif Central and the Apennines are mid mountain ranges with summits around 2000m whereas the Alps and the Pyrenees reach around 3000m on the Mediterranean side. When synoptic and lower-level conditions are favourable, this setting makes the whole region often subject to heavy precipitation events (HPEs) happening at local scales. Such events are characterized by large amounts of precipitation over a short period of time (typically more than 100mm in 24h recorded by raingauges), sometimes leading to flash-floods with damage and casualties. HPEs provide approximately 60% of the total seasonal precipitation (October to March) in the northern Mediterranean coastal area (Toreti *et al.* 2010).

They are linked with the large temperature contrast between the sea and the continent that favour instability in this season together with the transition from a subtropical regime in summer to the mid-latitude weather perturbation systems in winter. This also favours Mediterranean cyclones that were assessed to be linked with about 90% of the precipitation events with amounts larger than 60mm per day in the Western Mediterranean basin by Jansà *et al.* (2001). Cyclones, interactions with topography and self organisation of convection are typical mechanisms that can localize precipitation systems fed by low-level moist jets and induce very high precipitation amounts (García-Herrera *et al.* 2005; Houze 2004; Ducrocq *et al.* 2008; Pastor *et al.* 2010; Bresson *et al.* 2012; Ricard *et al.* 2012). This also most often involves a slow evolving large-scale trough that can become a cut-off low. Depending on the location of the trough, precipitation occurs in eastern Spain (Romero *et al.* 1999; Martínez *et al.* 2008; Riesco Martn *et al.* 2014), in Southern France (Nuissier *et al.* 2008; Toreti *et al.* 2010; Nuissier *et al.* 2011), in the Alps (Martius *et al.* 2008; Hoinka *et al.* 2006) or in Italy (Rudari *et al.* 2005).

Another characteristic of the Mediterranean area is the interaction between the orography and the large-scale flow that can generate strong winds (over 20 m s^{-1}) in the lower levels of the atmosphere (Chronis *et al.* 2011) through channeling and/or mountain wave overturning and eventual breaking. Local names have been given to these phenomena (Fig. 1c): in Spain the Cierzo (westerly wind in the Ebro valley), in France the Tramontane (westerly wind in the Aude valley, Drobinski *et al.* (2001)), the Mistral (northerly wind in the Rhône valley, Guénard *et al.* (2005, 2006); Drobinski *et al.* (2005)), in the Balkans the Bora (north-easterly wind across the Dinaric Alps, Grisogono and Belušić (2009)) or the Vandevoles in the Alboran sea. Other intense easterly or southeasterly winds occur during intense cyclonic circulation with less strong orographic interaction (Sirocco, Libeccio, Chili) blowing from Africa on Fig. 1c. All these

intense winds blow intermittently (Chronis *et al.* 2011; Herrmann *et al.* 2011) and generate intense air-sea fluxes (Flamant 2003; Lebeaupin Brossier and Drobinski 2009). They are mainly responsible for the large submonthly variability in the sea surface temperature (SST) of the Mediterranean together with the ocean circulation, the cloud cover and other mechanisms.

The wind strength necessary to create submonthly SST changes depends on the mixed layer depth, which varies between seasons and regions (Houpert *et al.* 2015) and on stratification. It also depends on the air-sea temperature and moisture contrasts and on the wind persistence (Lebeaupin Brossier and Drobinski 2009; Small *et al.* 2012). Anomalies after strong wind events can be persistent because of the heat capacity of the mixed layer which depends on its depth and the time needed for restratification (1 to 3 weeks). In the Gulf of Lions where a cyclonic gyre is present and enhanced by Mistral (Béranger *et al.* 2010), this last process can be important. As an example of cooling and persistence, Lebeaupin Brossier *et al.* (2013) study a case of Mistral in autumn in the Gulf of Lions with a coupled simulation when the simulated mixed layer was 50 m deep. 10 m s^{-1} winds blew for 2 days with peaks at 25 m s^{-1} . This led to total heat fluxes of 400 W m^{-2} on average over the northwestern Mediterranean lasting a whole day (Lebeaupin Brossier and Drobinski 2009). They caused the rapid breaking of the ocean surface stratification and then the mixing of the present subsurface cold waters isolated inside the gyre from the warmer surface waters. This cooling due to the entrainment at the mixed layer bottom was quantified to a cooling of 0.6°C.day which was 3 times larger than the cooling due to horizontal advection and 2 times larger than the one due to surface heat fluxes. This anomaly persisted for a week after the Mistral stopped.

This article addresses the question of whether or not these SST submonthly variations can influence HPEs in various regions.

Several studies investigated the sensitivity of HPEs to changes in the SST thanks to numerical mesoscale simulations. In the region of Valencia in Spain, Pastor *et al.* (2001) used different SST fields to force simulations of two cases. They show that an increase of SST upstream of the Valencia region (by 2 to 5°C) could lead to an increase (by a factor of 2) and a displacement of the precipitation maximum of a HPE. Pastor *et al.* (2015) further showed that for three HPEs in this same region, the SST area with the greatest influence on model precipitation results was the one situated between the Valencia coast and the Balearic Islands. It was shown that if intense heat/moisture air-sea exchanges were shut off by decreasing the SST to 10°C in this region, precipitation in Valencia were suppressed in 2 out of 3 cases. For these 3 cases, remote regions revealed a more moderate impact: switching off the fluxes had only an effect of modulation of the HPEs.

Millán *et al.* (1995) give another type of impact of the SST on precipitation. They infer that changes in SST have an impact on the convergence zone through the influence on the convective drag that occurs when colder continental air is advected over warmer SST (theory of the Back Door Front, (Millán *et al.* 1995)).

Figure 1. RMS of the submonthly variability of the SST (calculated as the deviation from the monthly moving average) for September to December, for the period 1989 to 2012 and for various datasets (CNR, OSTIA, ERA-Interim: see section 2.3) or simulations (WRCPL, ALCPL: see section 2.1.3).

Lebeaupin *et al.* (2006) showed with the help of high resolution numerical weather forecast simulations that a change in the mean spatial SST of 3°C had a strong influence on the intensity of rain events through changes in surface heat fluxes in three case studies over the Cévennes area. They also showed that the average upstream changes had more effect than changes in the very fine spatial structure of the SST. The mechanisms involved in the precipitation changes depend on the type of precipitation: for mesoscale convective systems (MCSs), the SST impacts on the intensity and location of convection whereas for quasi-stationary frontal systems, the response to the SST includes interaction between deep convection and frontal dynamics. Lebeaupin Brossier *et al.* (2013) used two regional climate twin simulations, one coupled to an ocean model and the other forced by low-resolution analyses. The SST differences between them were arising from both air-sea coupling and

from long-term biases of the oceanic model. These SST differences produced important modifications of precipitation during a HPE over the Cévennes. Using 20-year regional climate simulations, Berthou *et al.* (2014) were able to separate this long-term bias of the oceanic model from the submonthly air-sea coupling. They showed that statistically, at least for the HPEs represented by the model, a significant correlation exists between submonthly SST variations and modulation of the precipitation amount and location. Precipitation was more strongly impacted when the SST changes due to coupling effects were large. To explain dipole-like differences in the precipitation field, Berthou *et al.* (2015) showed the impact of SST changes on the low-level dynamics in regional climate simulations through i) impact on the blocking effect of the flow by the orography through changes in the low-level atmospheric stability; ii) impact on surface pressure through the convergence

of temperature anomalies; iii) direct impact on convergence zone dynamics by changes in the low-level atmospheric stability.

Katsafados *et al.* (2011) studied the effects of different SST forcings on a deep low-pressure system over the Eastern Mediterranean. Their results indicate that surface fluxes have a limited impact on the intensity and the location of this storm, mainly controlled by the upper atmospheric conditions. However, they note the existence of spatio-temporal deviations on the distribution of precipitation. The displacement of the rainbands appearing in the various experiments can possibly be associated with the simulated surface heat fluxes that induce stronger vertical momentum mixing responsible for mesoscale features in the surface wind convergence field.

Overall, these studies show that typical changes by a few degrees in the SST can modulate HPEs rather than act as a causal factor in their occurrence over the Mediterranean. This can be explained by the fact that the contribution of the Mediterranean to moisture feeding occurs over a few days before events occurring in Southern France (Duffourg and Ducrocq 2011). Therefore, a change of a few degrees in the SST may not significantly change the moisture and stability of the atmosphere: the preconditions mostly stay similar.

Regional climate models (RCMs) have proved to have some ability in representing mesoscale patterns of observed precipitation extremes that are constrained by the orography (Frei *et al.* 2006; Herrera *et al.* 2010; Colin 2012). In fact, Sánchez *et al.* (2004); Kysely *et al.* (2012); Rajczak *et al.* (2013) among others investigated the representation of extreme rain events and their projection into the future with RCMs. Moreover, coupled atmosphere-ocean RCMs (AORCMs) show good ability to reproduce strong wind episodes (Herrmann *et al.* 2011) and submonthly variations of SST (The PROTHEUS Group *et al.* 2009; Sevault *et al.* 2014). In this study, two AORCMs are used with different sets of simulations running over 24 years.

The Hydrological cycle in Mediterranean experiment (HyMeX) which aims at better understanding the water cycle in the Mediterranean (Drobinski *et al.* 2014) had a special focus on heavy precipitation events in autumn 2012 (from September 5 to November 4) with a measurement campaign (1st special observation period SOP1) described in Ducrocq *et al.* (2014). Six coastal regions of the Western Mediterranean basin were hit by at least one event of more than 100 mm as shown by the maximum precipitation recorded by the rain gauges (Fig. 2). This study will focus on these six regions:

- The region south of Valencia in Spain (Val)
- The foothills of the Massif Central in France called the Cévennes (Cvn)
- Liguria in Italy between Genoa and Florence (Li)
- Central Italy from Rome to Naples (CeIt)
- Calabria (Cal)
- Northeastern Italy around Trieste and Udine (NEI)

In the line of Berthou *et al.* (2014) who use regional climate simulations and study statistically the link

between changes in SST and changes in HPE in the Cévennes area, this study inquires if other regions show HPEs that are sensitive to SST changes, in particular SST submonthly variations. Moreover, this study also aims to give an index based on observed SST that could provide information on how strongly a HPE has been affected by submonthly variations of SST mainly due to local strong wind regimes blowing within a month of the event. In section 2, models, simulations and gridded products based on observations are described. In section 3 we examine the ability of the two regional climate models to represent the intensity and the chronology of HPEs as well as submonthly SST variations. This allows us to statistically assess the response of HPEs to variations in SST in section 4 and to compare the index based on the variations of the modeled SST to the ones based on the observed SST in section 5. Finally, we identify HyMeX HPEs that were potentially influenced by submonthly air-sea coupling thanks to this index and the relationship build in section 4.

2. Materials and methods

2.1. Models

2.1.1. MORCE platform

The MORCE (model of the regional coupled Earth system) platform is the first two-way air-sea coupled system (AORCM) used in this study (Drobinski *et al.* 2012). The MORCE system is used in HyMeX (Drobinski *et al.* 2014) and the Coordinated downscaling experiment (CORDEX) of the World climate research program (WCRP) (Giorgi *et al.* 2009) in the Mediterranean area (Med-CORDEX, Ruti *et al.* (2015)).

The atmospheric model within the MORCE system is the non-hydrostatic weather research and forecasting model (WRF) version 3.1.1 of the National Center for Atmospheric Research (NCAR) (Skamarock *et al.* 2008). The domain covers the Mediterranean basin in line with CORDEX requirements with a horizontal resolution of 20 km. It has 28 vertical levels from the surface to 50 hPa using sigma coordinates. The first 1000m are resolved on 8 levels.

The boundary layer parametrization is a K-profile scheme improved by Noh *et al.* (2003) (YSU). The surface-layer is the Monin-Obukov scheme (Stull 1994). The cumulus convection scheme is the Kain-Fritsch scheme (Kain 2004). It is a mass flux parametrisation scheme with a closure assumption based on CAPE. Convection is triggered when the temperature of a 60hPa layer is higher than the environment temperature at its condensation level. A temperature deviation is added to the parcel depending on the larger scale vertical velocity in order to trigger convection in a sub-cloud converging environment.

Two land surface models (LSM) have been used in this study, namely the Rapid Update Cycle (RUC) LSM and the thermal diffusion (DIFF) LSM. The RUC LSM (Smirnova *et al.* 1997) resolves heat and moisture transfer in 6 layers from 0 to 3 m. This scheme accounts for the different phases of soil surface water, vegetation effects (evaporation from leaf stomata, solar radiation

Figure 2. Rain maximum for every raingauge during HyMeX SOP1. Grey boxes indicate the regions selected for the study. Figure similar to Fig. 6 in [Ducrocq et al. \(2014\)](#).

absorption, heat fluxes etc.) and canopy water. The DIFF LSM is based on a 5-layer simple scheme where the energy budget includes radiation, sensible and latent heat. The last layer is only at 16 cm depth, under which the temperature is fixed at a deep-layer average. Vegetation effects are not taken into account. During the simulation, an empirical coefficient, called soil moisture availability is applied for latent heat flux calculation. It has been set to its wintertime values, therefore not permitting the simulation of soil moisture deficit situations. The complete set of physical parametrizations can be found in [Lebeaupin Brossier et al. \(2015\)](#) and [Stéfanon et al. \(2014\)](#).

The ocean model of MORCE is Nucleus for European Modelling of the Ocean (NEMO) ([Madec and the NEMO Team 2008](#)). It is used in a regional eddy-resolving Mediterranean configuration MED12 ([Lebeaupin Brossier et al. 2011](#); [Beuvier et al. 2012](#)) with a $1/12^\circ$ horizontal resolution, which represents about 6.5-7 km in the Gulf of Lions. In the vertical, MED12 has 50 stretched z-levels with a resolution of 1m for the surface layer. The initial conditions for 3D potential temperature and salinity fields are provided by the Mediterranean oceanic database version 4 (MODB4) climatology ([Brankart and Brasseur 1998](#)) except in the Atlantic zone between 11°W and 5.5°W , where the [Levitus et al. \(2005\)](#) climatology is applied. In this area, a three dimensional relaxation toward this monthly climatology is used. River runoff and the Black Sea water input come from a climatology ([Beuvier et al. 2012](#)) and their freshwater flux is set at the mouths of the 33 main rivers and at the Dardanelles Strait respectively. Smaller river runoffs are summed and set as a homogeneous coastal runoff around the Mediterranean Sea as in [Beuvier et al. \(2012\)](#). Further details on the ocean model parametrization can be

found in [Beuvier et al. \(2012\)](#) and [Lebeaupin Brossier et al. \(2013\)](#).

2.1.2. The CNRM regional climate system model: CNRM-RCSM4

The coupled regional climate system model developed at CNRM ([Nabat et al. 2015](#); [Sevault et al. 2014](#)) includes the regional climate atmospheric model ALADIN Climate version 5 ([Colin et al. 2010](#); [Herrmann et al. 2011](#)), the land surface model ISBA ([Noilhan and Mahfouf 1996](#)), the river routing scheme TRIP ([Decharme et al. 2010](#)) and the regional ocean model NEMO-MED8 ([Beuvier et al. 2010](#)).

The ALADIN-Climate model is a bi-spectral regional climate model with a semi-implicit semi-Lagrangian advection scheme. A 2-D bi-Fourier decomposition is used ([Haugen and Machehauer 1993](#)). The convection scheme is a mass-flux scheme with convergence of humidity closure based on [Bougeault \(1985\)](#). The triggering function for convection is based on CAPE and moisture convergence. The cloud scheme is based on the [Ricard and Royer \(1993\)](#) statistical scheme and on the large-scale precipitation described by [Smith \(1990\)](#). The radiative scheme is derived from [Morcrette \(1989\)](#) and from the IFS model of the ECMWF. The planetary boundary layer turbulence physics including the computation of the turbulent air/sea fluxes is based on [Louis \(1979\)](#), and the interpolation of the wind speed from the first layer of the model (about 30 m) to the 10 m height follows [Geleyn \(1988\)](#). The domain has a Lambert conformal projection at a horizontal resolution of 50 km centered at 14.8°E , 43.8°N with 128 longitude grid-points and 90 latitude grid-points including the biperiodisation (11 grid-points) and the relaxation zones (2×8 grid-points). The ISBA

model is the land-surface scheme interfaced with the atmospheric model. This version of the model has 31 vertical levels. The time step used is 1800 s.

The ocean model NEMO-MED8 (Beuvier *et al.* 2010) is a regional version of the NEMO-V2.3 ocean model (Madec and the NEMO Team 2008). NEMO-MED8 covers the Mediterranean Sea (without the Black Sea) plus a buffer zone including the adjacent part of the near Atlantic Ocean, where a three-dimensional damping is performed towards temperature and salinity (monthly data, NEMOVAR-COMBINE, Balmaseda *et al.* (2010)), so that the circulation through the strait is simulated with realistic Atlantic waters. A sea level relaxation is also applied on this Atlantic part of the domain towards the same reanalysis. This version has a horizontal resolution between 9 and 12 km, and 43 vertical levels, with layer thickness increasing from 6 m to 200 m. The partial steps definition of the bottom layer is used, and the surface is parameterized with the free surface configuration, filtered formulation.

The TRIP river routing model is used to convert the simulated runoff by the ISBA land surface scheme into river discharge using a river channel network at 0.5° resolution (Decharme *et al.* 2010). Coupling between all the different components is achieved by the OASIS3 coupler (Valcke 2013) at a one day frequency.

2.1.3. Configuration of MORCE and CNRM-RCSM4 and simulations

For each model, one atmosphere-ocean fully coupled simulation and one atmosphere-only simulation forced by ERA-Interim SST are run. We call them respectively CPL and CTL simulations in the rest of the study. In the atmosphere only simulations, SST from ERA-Interim is updated every day in WRF and every month in ALADIN (Table 1). Thus, the daily difference between the SST of NEMO in the coupled simulations and ERA-Interim in the atmosphere-only simulations can be much larger for CNRM-RCSM4 than for MORCE (see Fig. 3). A third simulation called SMO (for monthly-smoothed SST) was run with MORCE. SMO is an atmosphere-only simulation with the same characteristics as the CTL simulation, except that instead of the ERA-Interim SST, a new SST field has been used for the forcing of the atmospheric model. This forcing has been designed in order to retain the same climatology and diurnal cycle as the CPL SST, but without the submonthly SST variations. For that purpose, the SST value used to force the RCM at each target time step was calculated by performing a central moving average with a 31-day window, retaining only the 31 time steps in the time window that correspond to the same GMT time as the target time step. This way, the diurnal cycle (as well as its seasonal variations) is preserved, as are all the persistent spatial structures that exist in CPL. The high-frequency air-sea coupling effects (submonthly variations), however, are not present in SMO (Fig. 3).

CNRM-RCSM4 simulations run from 1979 to 2012 but the period used in this study is 1989-2012. We will call them ALCPL for the coupled version and ALCTL for the version forced with the ERA-Interim SST. MORCE is used with two soil schemes: RUC and

DIFF. Each version of the model is run 3 times in CPL, CTL and SMO configurations. WRCPL, WRCTL and WRSMO are the versions with the RUC surface scheme from 1989 to 2012 and WDCPL, WDCTL and WDSMO are the versions with the DIFF surface scheme from 1989 to 2008. Table 1 sums up all the simulations used.

For both atmospheric models, initial and lateral conditions are taken from the European Centre for Medium-Range Weather Forecasts (ECMWF) ERA-Interim reanalysis (Simmons *et al.* 2007) provided every 6 h with a 0.75° resolution.

Nudging above the boundary layer is used by both models in order to avoid a large-scale that would diverge from the observed large-scale structures inside the limited area (Stauffer and Seaman 1990; Salameh *et al.* 2010; Omrani *et al.* 2013). The main disadvantage of this technique is to dampen the response of the free troposphere to surface changes. However, the major advantage is that the large-scale still respects the ERA interim one and the chronology of events is similar between two simulations that have different surface boundary conditions (Herrmann *et al.* 2011). In MORCE, indiscriminate nudging (Newtonian-type nudging) is used to constrain the fields above the planetary boundary layer with a coefficient of $5 \cdot 10^{-5} s^{-1}$ (about 5.5 h) for temperature, humidity and velocity components. The nudging coefficient was chosen following Omrani *et al.* (2013) so that the relaxation time is large enough to constrain the large scale without prohibiting small-scale evolution. CNRM-RCSM4 uses a spectral nudging technique (Herrmann *et al.* 2011; Sevault *et al.* 2014). Temperature, specific humidity, wind vorticity, wind divergence and the logarithm of the surface pressure are nudged with a respective maximum e-folding time of 24 h, 24 h, 6 h, 48 h and 24 h. The maximum e-folding time is reached above 700 hPa and for larger scales of 1280 km. The nudging linearly decreases between 700 and 850 hPa in altitude and 1280 and 640 km in horizontal scales. Therefore, the scales smaller than ERA-Interim scales are not nudged.

In the MORCE model, the ocean starts from 3D potential temperature and salinity fields provided by the MODB4 climatology (Brankart and Brasseur 1998) in 1989 while a 21 year spin-up is performed in CNRM-RCSM4 using the 1980-1986 period in a three-time loop period (Sevault *et al.* 2014) before starting in 1979. This means that the ocean starts at rest and is forced by the atmospheric fields of 1980-1986 three times in a row.

The two versions of WRF show strong differences in the 2 m temperature, especially in summer where the simulations using DIFF LSM show weaker temperatures by 5-6°C over continental surfaces compared to the ones using RUC LSM (Flaounas *et al.* 2013): this potentially has an impact on the atmospheric stability. The two WRF configurations result in very different land surface conditions and add a member in the analysis of the response of precipitation to SST changes.

The comparison between CPL and CTL at the daily scale will mainly indicate the impact of a different SST on the atmospheric field. This different SST comes

Figure 3. Averaged SST over the upstream region of the Cévennes (red box in Fig. 4) for the month of October during HyMeX SOP1 for different datasets. Periods of northerly or northwesterly wind (Mistral) above 10 ms^{-1} in WDCPL are highlighted in grey, periods of HPE occurring in the blue box in Fig. 4 are highlighted in red.

from both coupling effects and long-term biases in the model (Sevault *et al.* 2014; Lebeaupin Brossier *et al.* 2015), in addition to the monthly SST update in ALADIN. WDCPL and WRCPL show quite different biases and are therefore interesting to compare in the rest of the study. The comparison of CPL with SMO for MORCE will permit a more physical interpretation since differences arise only from coupling at the submonthly scale (e.g. strong wind bursts cooling the SST).

2.2. Gridded rain datasets

In order to evaluate the models in terms of extreme precipitation events in the 6 regions selected for this study (in section 3.1), different regional gridded datasets based on rain gauges were used and are presented hereafter. Table 2 shows which dataset was used for each region;

2.2.1. SAFRAN (France)

Système d’analyse fournissant des renseignements atmosphériques à la neige (SAFRAN) is a precipitation analysis for continental France that uses an optimal interpolation method. One of the main features of SAFRAN is that the analyses are performed over climatologically homogeneous zones, which are areas of irregular shape covering a surface usually smaller than 1000 km^2 and where the horizontal climatic gradients (especially for precipitation) are weak. SAFRAN estimates one value of each parameter for each zone at several altitude levels. Within the zone, analyzed parameters depend only on elevation and aspect. First, SAFRAN performs a quality control of the observations. This is an iterative procedure based on the comparison between observed and analyzed quantities at the observation location. There were 3675 measurement stations for 2004/05. The precipitation analysis is performed daily at 0600 UTC, to include in the analysis the numerous rain gauges that measure precipitation on a daily basis (in particular in the climatological and snow networks). The first guess is a very simple and constant field. An hourly separation is then performed but in this study we use the daily

precipitation amount. Further description can be found in Quintana-Seguí *et al.* (2008).

2.2.2. Alps dataset

The Alpine rain gauge dataset typically comprises 5500 observations on any day of the period 1971-2008. The analysis is based on a first guess for a day that is the long-term mean precipitation (period 1971-1990) of the relevant calendar month. The precipitation-elevation relationship is calculated locally and taken into account in this first guess. Then, an anomaly is computed for every grid point using the stations located within a radius that depends on the station density. It can be up to 60 km from the grid point. The dataset has a 5 km resolution but its effective resolution is closer to 10-15 km. The dataset is provided by the Federal Office of Meteorology and Climatology MeteoSwiss. Further description can be found in Isotta *et al.* (2014).

2.2.3. Spain02

Spain02 is a high-resolution (0.2°) daily precipitation gridded dataset developed for peninsular Spain and the Balearic islands using 2756 quality-controlled stations over the time period from 1971 to 2010 (Herrera *et al.* 2012). The grid was produced applying the kriging method in a two-step process. First, the occurrence was interpolated using a binary kriging and, in a second step, the amounts were interpolated by applying ordinary kriging to the occurrence outcomes. The elevation is not explicitly included in the development of the dataset because the available dense gauge network appropriately represents the orography corresponding to the 0.2° grid. Explicit comparison with E-OBS dataset shows the better performance in terms of amount and spatial distribution of Spain02 to capture extreme events, especially in the region of Valencia (Herrera *et al.* 2012).

2.2.4. E-OBS

The European Climate Assessment and Data set (ECA&D) project called (E-OBS) integrates data for 62 countries at 4823 meteorological stations throughout Europe and the Mediterranean area. The gridded dataset is produced with a horizontal resolution of 0.25° by 0.25° . Haylock *et al.* (2008) describe the method used to compute the gridded product: it is a three-step process of interpolation. First the monthly precipitation totals are interpolated using three-dimensional thin-plate splines, then the daily anomalies are interpolated using indicator and universal kriging and finally the monthly and daily estimates are combined.

This dataset covers the whole of Europe but uses a coarser spatial density of stations than the gridded products presented before. It is therefore used for the two regions in Italy which are not covered by the other datasets: Calabria and Central Italy. Only 2 stations are located in Calabria at the eastern edge of the region and 5 stations are used for Central Italy.

Shortname of the set	Shortname of the simulation	Atmosphere	SST	SST update	surface	time span
ALADIN	ALCTL	ALADIN (50km)	ERA-Interim (80km)	monthly	ISBA	1989-2012
	ALCPL	ALADIN (50km)	NEMO-MED8 (9-12km)	daily	ISBA	1989-2012
WD	WDCTL	WRF (20km)	ERA-Interim (80km)	daily	DIFF	1989-2008
	WDCPL	WRF (20km)	NEMO-MED12 (6-9km)	3 hourly	DIFF	1989-2008
	WDSMO	WRF (20km)	monthly smoothed CPL SST	6 hourly	DIFF	1989-2008
WR	WRCTL	WRF (20km)	ERA-Interim (80km)	daily	RUC	1989-2012
	WRCPL	WRF (20km)	NEMO-MED12 (6-9km)	3 hourly	RUC	1989-2012
	WRSMO	WRF (20km)	monthly smoothed CPL SST	6 hourly	RUC	1989-2012

Table 1. Summary of the different simulations used in the study and their configurations. See section 2.1.3 for further details.

Region	Gridded dataset used	Resolution	Period of interest covered
Valencia	Spain02	25 km	01/01-1989 to 31/12/2010
Cévennes	SAFRAN	8 km	01/01/1989 to 31/07/2010
Liguria	Alps dataset	5 km	01/01-1989 to 31/12/2008
Central Italy	E-OBS	25 km	01/01-1989 to 31/12/2012
Calabria	E-OBS	25 km	01/01-1989 to 31/12/2012
Northeastern Italy	Alps dataset	5 km	01/01-1989 to 31/12/2008

Table 2. Summary of the different gridded rain datasets used in the study.

2.3. SST datasets

These SST products are built with satellite and in-situ observations and are used for comparison with the SST produced by the coupled models, with a focus on submonthly variations of SST (section 3.2 and section 5).

2.3.1. CNR SST

The first dataset covering the whole period 1989-2012 in SST of the Western Mediterranean basin is the one computed by the CNR-ISAC-GOS (Consiglio Nazionale delle Ricerche, Istituto di Scienze dell'Atmosfera e del Clima - Gruppo di Oceanografia da Satellite, Italy) (CNR-ISAC-GOS REP L4, described in Buongiorno Nardelli *et al.* (2014)). We will name it CNR SST. The data corresponds to daily (night-time) gridded optimally interpolated satellite estimates of the foundation SST over the Mediterranean, based on AVHRR Pathfinder Version 5.2 (PFV52). The interpolation is done on the original Pathfinder grid (at 4 km x 4 km spatial resolution). The SST analysis is then obtained as a linear combination of the observations, weighted directly with their correlation to the interpolation point and inversely with their cross-correlation and measurement error. The chosen scheme uses a daily decadal climatology as first guess (built from the entire PFV52 dataset), and a covariance model that assumes spatially varying parameters. The input data is selected only within a limited sub-domain (within a space-time influential radius), namely within a temporal window of ten days and a spatial influential radius ranging between 300 and 900 km.

2.3.2. OSTIA SST

The Operational Sea surface Temperature and Ice Analysis (OSTIA) provides daily gap-free

maps of foundation sea surface temperature at 0.05° x 0.05° horizontal resolution, using in-situ and satellite data from infra-red radiometers. Satellite data are provided by the Pathfinder AVHRR project and reprocessed (A)ATSR data from 1985 to 2007, together with MetOp satellites, SEVIRI, GOES-East, TMI, IASI after 2007. In-situ observations come from the ICOADS data-set (drifters, ships, moored buoy). These observations may not be very numerous in the Mediterranean. Moreover, a bias correction on the observations is performed using ATSR-2/AATSR data as a key component. To provide the final SST analysis, a multi-scale optimal interpolation (OI) is performed using the previous analysis as the basis for a first guess field for the reanalyses before 2007 and using the previous analysis with a slight relaxation to climatology after. It is run daily at 06 UTC using data from a 36-h period using two error correlation scales, 10 and 100 km, which vary depending on the region and the input data. When compared to in situ observations in the Mediterranean, mean difference is 0.11°C and standard deviation is 0.89°C which is the worst score for all the OSTIA regions covered (Donlon *et al.* 2011). Further information is provided by Roberts-Jones *et al.* (2012); Donlon *et al.* (2011).

2.3.3. ERA-Interim SST

ERA-Interim SST is not homogeneous in time: from January 1989 to June 2001, NCEP 2D-Var sea surface temperature (NCEP 2D-Var) is used. From July 2001 to December 2001, NOAA Optimum Interpolation Sea Surface Temperature v2 (NCEP OISST v2) is used. From January 2002 to January 2009 NCEP Real-Time Global sea surface temperature (NCEP RTG) is used. Finally, OSTIA is used from 2009 to 2012 (Dee *et al.* 2011).

3. Evaluation of the models

Since this study focuses on the effects of submonthly variations of SST on heavy precipitation events, it is necessary to first give an evaluation of the representation of both phenomena in the RCMs compared to the available gridded datasets.

3.1. Selection and representation of heavy precipitation events

Six regions were selected for the study (Fig. 2). An evaluation of the models for all the regions is given here. A more thorough analysis is provided for the south of France in Colin (2012) for ALCTL. Time series of the spatial maximum of daily precipitation (from 0600 UTC to 0600 UTC) within each region were first computed. A threshold was then defined in the temporal series of spatial maxima to get the largest daily precipitation events that occurred in every simulation for the time period from 01/01/1989 to the end of the simulation. For the events exceeding the precipitation threshold for a number of consecutive days, only the day with the maximum precipitation was selected. 30 events were selected for ALCPL and WRCPL simulations which end on 12/31/2012 and 25 for WDCPL which ends on 12/31/2008 so that the number of events is 1.25 per year. The gridded datasets described in section 2.2 were regridded on each model grid by bilinear interpolation and the same selection was done. Table 3 shows the thresholds that were chosen for the simulated precipitation and the gridded precipitation datasets. One threshold was chosen for every set of simulations so that the CPL simulation contains 30 events. This number was chosen in order to get a significant number of events and to avoid too many non HPEs, as shown later in this section.

The main conclusion is that for the regions where the model is compared with gridded products based on a high density network of rain gauges, i.e. Valencia, Cévennes, Northeastern Italy and Liguria, both models underestimate heavy precipitation even when the gridded precipitation has been regridded at the model resolution, in agreement with previous studies (Déqué and Somot 2008; Colin 2012; Prein *et al.* 2015a). This shows that many small-scale processes enhancing precipitation during heavy rain events are missing in RCMs, probably due to a lack of resolution of topography and a lack of representation of small-scale effects (Déqué and Somot 2008; Prein *et al.* 2013) such as convective cold pools (Ducrocq *et al.* 2008). The amount of rain in Valencia is better represented with an underestimation of 30% for ALCPL and an overestimation by 15% by WRCPL. On the contrary, Northeastern Italy shows the largest differences, with the model thresholds being respectively 55% and 58% of the dataset thresholds. Small-scale processes seem to have a greater impact on precipitation in this region, maybe because of its steeper orography, smoothed by the model. Regarding Calabria and Central Italy, the E-OBS dataset is based on a few rain gauges and unlike in the other regions, the threshold in the dataset is lower than in both models. Flaounas *et al.* (2012) showed that E-OBS underestimates station rainfall extremes by 20 to 60 mm in coastal stations located

in southern France. It is highly possible that this is also what is observed here.

A great advantage of nudged simulations is that the chronology of ERA-Interim is well respected and the downscaled HPEs can be dated. Table 4 shows the hit rates (HR) of the different simulations. The hit rate is calculated as the ratio of the number of events represented by the model and recorded in the reference dataset to the total number of events in the reference dataset. The target value of the hit rate is 1, meaning that all the observed events are captured by the model.

The simulations show a hit rate larger than 0.4 for every region except Liguria for the comparison with high quality datasets. Prein *et al.* (2015a) also show that the intensity of the 97.5 percentile of precipitation in Liguria is underestimated by RCMs with 12.5 km and 50 km grid spacing respectively by 25% and 35% in SON. Again in Calabria (HR around 0.3) and even more in Central Italy (HR around 0.2), the scores are low but it is hard to attribute these deficiencies to the models or to the dataset since the dataset shows a lower threshold than the model and may not capture all the extreme events happening in these regions due to a low density of rain gauges. Flaounas *et al.* (2012) also show that the rainy days are not the same between E-OBS and independent rain gauges, which suggests low reliability in the selection of HPEs in these regions using E-OBS.

Given these HR, it is worth knowing whether or not the events that are identified as extreme in the models but not in the dataset are still HPEs. Table 5 shows the percentage of events represented by the model that are among the 100 largest events in the reference dataset. The scores larger than 70% and up to 88% show that most of the events that the models represent are actually events when intense precipitation occurred. Therefore in these regions, we can consider that RCMs are good enough for the study of HPEs. Liguria is the only region where the models do not seem to be able to represent HPEs correctly. Calabria and Central Italy also show weak results but it is not clear whether the errors come from the models or from the dataset. Therefore, Calabria and Central Italy will be retained but Liguria will not be considered for the rest of the study.

3.2. Representation of the submonthly variations of SST

In the previous section, the HPEs were selected throughout the year. However, in the dataset, 78% of the selected events occur from September to December. In the models, this figure is 71% in WRCPL, 74% in WDCPL and 70% in ALCPL. Therefore, the submonthly variations of SST are shown for this period. However, it is important to keep in mind that even though intense wind events are more frequent in winter (Chronis *et al.* 2011), submonthly variations of SST are stronger when the thermocline in the ocean is stronger and closer to the surface in summer and weaker when the thermocline is weaker and deeper in winter (Houpert *et al.* 2015). In Fig. 1, the root mean square (RMS) of the submonthly variations of SST is shown for each simulation or dataset. It is the RMS of the difference of the daily time

	Cévennes	Valencia	Calabria	Central Italy	Northeastern Italy	Liguria
ALCPL	62	40	54	47	66	57
dataset 50km	117	56	26	36	119	91
WRCPL	114	90	100	81	103	90
dataset 20km	138	78	31	42	175	147

Table 3. Threshold (mm day^{-1}) used in simulations and in the regridded precipitation dataset on a 20 or 50 km grid to select the HPEs (Table 2 gives the rain dataset used for each region).

	Cévennes	Valencia	Calabria	Central Italy	Northeastern Italy	Liguria
WRCPL	0.48	0.46	0.23	0.25	0.44	0.18
WRCTL	0.44	0.48	0.20	0.30	0.44	0.18
ALCPL	0.41	0.41	0.27	0.30	0.48	0.24
ALCTL	0.47	0.42	0.23	0.36	0.41	0.20

Table 4. Hit rate for every simulation between the 30 heaviest precipitation events in the simulation and the 30 heaviest precipitation events in the precipitation dataset regridded at each model resolution.

series of SST and a monthly smoothed time series during the period 1989-2012. All the panels show that the Mistral and Tramontane bring the strongest submonthly variability in the Mediterranean, with mean submonthly variations up to $0.4\text{--}0.6^\circ\text{C}$ in the Gulf of Lions and the French Riviera. In addition, the Northern (or Liguro-Provençal) Current flows along the northern coasts from Liguria to Catalonia, and partly comes back to form the cyclonic gyre in the Gulf of Lions, partly cyclonically veers towards the Balearic coasts and partly goes on to the Alboran sea (Millot 1999). Its meanders and the appearance of anticyclonic eddies along the Catalan coast with lifespan of a few weeks are also responsible for the submonthly variability in the Ligurian sea, the Gulf of Lions and the Balearic sea (Garreau *et al.* 2011; Lebeaupin Brossier *et al.* 2014). Mistral/Tramontane winds also influence the Tyrrhenian SST submonthly variations together with the cyclonic eddy present off the Strait of Bonifacio (Millot 1999; Small *et al.* 2012), where submonthly variations reach 0.4 to 0.5°C . The Adriatic sea shows mean variations of $0.4\text{--}0.5^\circ\text{C}$ linked with the Bora wind. The Alboran sea also shows 0.3 to 0.5°C of submonthly variations, linked both with the presence of large eddies and to the Vandevoles. All other regions show submonthly variations of 0.2 to 0.4°C . To get an idea of the seasonal cycle of these variations, the submonthly variations of SST in the Gulf of Lions range from 1° in summer to 0.4° in winter (not shown).

The CNR dataset in Fig. 1a, which is a product especially designed for the Mediterranean sea, shows the strongest amplitude of submonthly variations among all the datasets (CNR, OSTIA and ERA-Interim). It is stronger by 0.1°C compared to OSTIA (Fig. 1b) in all the considered regions and shows a thinner spatial structure than OSTIA, though the global pattern is similar. ERA-Interim (Fig. 1e), used in all CTL simulations fails to capture the fine scale structure and the amplitude of the submonthly variations.

The two CPL simulations WRCPL (Fig. 1c) and ALCPL (Fig. 1d) show coherent spatial structures with OSTIA and CNR with the effect of Mistral/Tramontane, the Bora and Vandevoles. However, their intensity is closer to OSTIA than to CNR. They both seem to underestimate submonthly variations in the southern part of the Mediterranean, notably in the Ionian sea by 0.1 to 0.2°C . ALCPL shows better ability to reproduce the submonthly variations in the Gulf of Lions than WRCPL in this season.

The models perform reasonably well in representing HPEs in the Cévennes, Valencia and Northeastern Italy (Calabria and Central Italy can not be well evaluated) and submonthly variations of SST in the western Mediterranean basin, although they tend to underestimate them. Therefore, they are a valuable tool to study the impact of submonthly variations of SST on heavy rain events in these regions.

4. Response of HPEs to variations in SST

The approach used to identify whether or not the HPEs selected in the simulations were sensitive to changes in the SST is to compare the different simulations that were run for each model. In fact, the nudging technique applied to the model allows the large scale fields above the boundary layer to respect the ERA-Interim fields so that simulations with different surface conditions still have the same large scale fields but differ from the boundary layer response. Tables 4 and 5 confirm these results with similar HRs between CTL and CPL simulations. In order to get synthetic indexes of SST and rain differences, the methodology developed in Berthou *et al.* (2014) is adopted. A zone of precipitation differences of 60000 to 65000 km^2 is defined around the zone where extreme events were selected for each region (blue boxes in Fig. 4). It corresponds to the zone encompassing most intense precipitation that occurred among the selected events as shown by the occurrences of precipitation greater than 50 mm (blue contours in Fig. 4).

	Cévennes	Valencia	Calabria	Central Italy	Northeastern Italy	Liguria
WRCPL	88	81	47	41	87	41
WRCTL	88	77	43	45	82	45
ALCPL	85	70	39	53	71	39
ALCTL	81	69	52	41	70	34

Table 5. Percentage of events represented by the model that are among the 100 largest events in the reference dataset

Eq. (1) shows the calculation to define the I_{rain} index that measures precipitation difference between two simulations in the box previously defined. It is the spatial RMSE between two simulations in a certain zone and allows dipoles of precipitation differences not to each other cancel out.

$$I_{\text{rain}} = \sqrt{\delta P^2 \text{Reg}_{\text{Precip}}} \quad (1)$$

where δP represents the daily precipitation difference between two simulations (CPL-CTL or CPL-SMO) and $\text{Reg}_{\text{Precip}}$ names the zone on which the spatial average is performed, i.e. the zone defined in blue in Fig. 4.

The same method is used for the SST in an area upstream of the precipitation event, defined as a function of the upstream low-level jets for each zone. The zones are shown in Fig. 4 with a thick red line. They are defined as the zones where most occurrences of winds larger than 10 ms^{-1} are located, i.e. where most low-level jets feeding the events are located. The longest dimensions of these zones are between 550 km and 800 km, which means a residence time in the zone of the order of 15 to 22 h with a low-level wind speed of 10 ms^{-1} . Flux differences between simulations can therefore be large and last for half a day under this low-level jet. Thus, the hypothesis based on the work of Berthou *et al.* (2014) is that these zones influence the low-level jet dynamics through the generation of pressure anomalies and stratification changes arising from changes in surface fluxes colocalised with SST changes. For Central Italy, either the zone in the Adriatic sea or in the Tyrrhenian sea (Fig. 4) is used depending on the direction of the incoming flow (in ALCPL about 60% and in WRCPL about 50% of the events come from the Adriatic sea).

Berthou *et al.* (2014) showed the efficiency of taking a SST difference index as defined in Eq. (2).

$$\text{IPSS} = \sqrt{\delta SST^2 \text{Reg}_{\text{SST}}} \quad (2)$$

where δSST represents the mean daily SST differences on the day of the HPE between two simulations (CPL-CTL or CPL-SMO) and Reg_{SST} is the zone on which the average is performed, i.e. the zone outlined in red in Fig. 4.

Since these indexes are sensitive to the model resolution, the precipitation and SST fields of WRF at 20 km resolution were regridded on ALADIN grid at 50 km resolution before the calculations.

In Fig. 5 and Fig. 6, I_{rain} divided by P_{max} (the daily precipitation maximum in the rain box in the model) is plotted against the IPSS. This relative I_{rain} (referred as i_{rain} from now on) allows the comparison between

models which do not produce the same maximum precipitation intensity. Each cross is a single event for CPL-CTL in Fig. 5 and CPL-SMO in Fig. 6 respectively. CPL-CTL (Fig. 5) shows changes of SST due to multiple effects, the dominant one being the different SST climatology between the coupled model and ERA-Interim since the coupled model has no assimilation of observed SST. CPL-SMO (Fig. 6) shows the effect of SST changes arising from submonthly coupled effects (in this region, mainly changes due to Mistral and Tramontane wind regimes).

The figures for the Cévennes (Fig. 5a and Fig. 6a) show similar results as in (Berthou *et al.* 2014) for WDCPL-WDCTL and WDCPL-WDSMO: the changes in precipitation amounts are proportional to the changes in SST in the model (the Pearson correlation coefficients are shown in Table 6). The submonthly coupled effects are weaker than changes of climatology (IPSS up to 1.2°C for CPL-SMO vs 2°C for CPL-CTL) but can still show a relative i_{rain} of 0.085. The slope for ALCPL-ALCTL is also present and robust (Table 6) and it is similar to the WDCPL-WDCTL one (Fig. 5a). The same calculations for WRCPL-WRCTL show a less robust slope (Table 6) with smaller IPSS values due to smaller SST biases in the model for this region but the slope is still similar to WDCPL-WDCTL. It is worth noting at this point that SST biases in WDCPL are much larger than in WRCPL, allowing the examined statistical relationship to be extended to include larger IPSS values for the Cévennes and Valencia areas.

This study also extends the study carried out in Berthou *et al.* (2014) to other regions than the Cévennes. Fig. 5 and Table 6 show that linear relationships between IPSS and the relative i_{rain} are obtained by both models in Valencia and Calabria together with the Cévennes. Central Italy shows a more random sensitivity to IPSS. Fig. 4d shows the two zones used in Central Italy to calculate the IPSS: one in the Adriatic when the wind feeding the precipitation system comes from this region and one in the Tyrrhenian sea when the incoming low-level jet is westerly. The two different symbols for the HPEs fed by these two different zones do not show more sensitivity from one zone compared to the other. Therefore, SST variations in these upstream zones may not have a direct effect on precipitation in Central Italy. Northeastern Italy shows a weak sensitivity to SST changes in all models except for a few events. The upstream trajectory of the low level jet is mixed between land and sea due to the configuration of the region. Therefore, the Adriatic sea seems to have a weak effect on precipitation in most cases.

Figure 4. In blue contours: occurrences of daily rain greater than 50mm among the selected events, contour every 5 occurrence. In red contours (resp. dashed red contours): occurrences of surface wind intensity larger than 10 m s^{-1} (resp. 15 m s^{-1}) among the selected events, contour every 5 occurrence, first contour for 15 occurrences. Total number of events is around 30 (selected with the thresholds presented in Table 3). The box in thick blue lines shows the zone selected for calculating the rain differences between simulations (I_{rain}) and the box in thick red lines shows the zone selected for calculating the SST differences between simulations (IPSS). Results are shown for WRCPL.

Looking specifically at the sensitivity of HPE to submonthly variations of SST in Fig. 6 using CPL-SMO, we can conclude from this study that the Cévennes, Valencia and Calabria show a robust relation between relative i_{rain} and IPSS. The slopes are stronger in Valencia and Calabria than in the Cévennes: an IPSS

of 0.5°C leads to a relative i_{rain} of about 0.08 (against 0.04 for the Cévennes). Valencia is the region with the strongest IPSS and the strongest relative changes in precipitation (up to 0.30). Calabria, though presenting a similar slope, shows weaker IPSS in the Ionian sea. In Central Italy, the relation is more random, as

Figure 5. Relative i_{rain} calculated for every event in the zone named above each panel and plotted against the index of SST differences in the corresponding SST zone for WDCPL-WDCTL (blue x crosses), WRCPL-WRCTL (red + crosses), ALCPL-ALCTL (black circles). Each cross is one event as selected in Table 3.

its was for CPL-CTL. Northeastern Italy shows very weak sensitivity of precipitation to SST submonthly variations.

Sensitivity of the results to the choice of boxes was tested for the Cévennes region in Berthou *et al.*

(2014) and the relationship was shown to be robust for locations of the SST box down to the Balearic Islands.

Several tests on the shape of precipitation and SST zones within the regions where they are defined were

Figure 6. Same as Fig. 5 for WDCPL-WDSMO (blue x crosses), WRCPL-WRSO (red + crosses). Note the scale difference.

done with no loss of robustness in the relationship (not shown).

The events were selected throughout the year with no preferable season, though more than 70% occur from September to December. There is no evident difference of sensitivity to the SST between events in different

seasons: less numerous, the points out of the main season are no outliers in the plots (not shown).

4.1. Wind changes are mainly responsible for precipitation changes

Changes in moisture convergence.

	Cévennes	Valencia	Calabria	Central Italy	Northeastern Italy
WDCPL-WDSMO	0.89	0.79	0.67	0.16	0.51
WDCPL-WDCTL	0.60	0.69	0.71	0.26	0.11

WRCPL-WRSMO	0.62	0.68	0.41	0.38	0.31
WRCPL-WRFCTL	0.45	0.44	0.28	0.13	0.02

Table 6. Pearson correlation coefficients R calculated between relative i_{rain} and IPSS ($^{\circ}\text{C}$) (defined in Eq. (2)) with IPSS calculated on the different regions defined in Fig. 2. Statistically significant coefficients of correlation above 99% using a Student-t test are indicated with bold font.

Berthou *et al.* (2014, 2015) showed in two case studies that the mechanisms linking SST differences to precipitation differences did not come directly from changes in the air moisture that could change the precipitation amount but from changes in the wind dynamics that were responsible for the convergence of moisture. Three mechanisms were highlighted: changes in SST imply changes in surface fluxes under the low-level jet, which results in convergence of temperature anomalies, themselves responsible for pressure anomalies in the convergence zone that can shift the place of this convergence zone where precipitation occur. The two other mechanisms are linked with changes in stratification of the incoming flow. This can change the intensity of the flow deviation by high orography. Changes in stratification can also change the dynamics of the low-level convergence, that can also be shifted through this mechanism. These mechanisms were highlighted for case studies in the Cévennes region but the results of this study (other regions also present similar linear relationships between changes in rain and changes in SST in the upstream region) raises the question of whether or not changes in precipitation are also explained by wind changes rather than by changes of the moisture content of the low-level jet in all regions and models.

To answer this question, we computed the low-level moisture convergence in the precipitation zone as such:

$$M_{cvg}^X = -\nabla(\mathbf{u}_X Q_X) \quad (3)$$

where X stands for the simulation name (CPL or CTL), $\mathbf{u}$ is the daily-mean vector of near-surface horizontal wind, Q is the daily-mean near-surface specific humidity field. Then, the same kind of index is computed as for the rain or SST:

$$I_M = \sqrt{(M_{cvg}^{CPL} - M_{cvg}^{CTL})^2}^{Reg_{SST}} \quad (4)$$

This I_M shows the amount of difference in moisture convergence between the two simulations CPL and CTL.

In order to identify whether or not changes in moisture or changes in the wind are the dominant part of the changes in the moisture convergence, we compute M_{cvg} while keeping one of the fields: $\mathbf{u}$ or Q from the CTL simulation:

$$MQ = -\nabla(\mathbf{u}_{CTL} Q_{CPL}) \quad (5)$$

$$MU = -\nabla(\mathbf{u}_{CPL} Q_{CTL}) \quad (6)$$

From these two new variables, we compute two new indexes:

$$IU = \sqrt{(M_{cvg}^{CPL} - MQ)^2}^{Reg_{SST}} \quad (7)$$

$$IQ = \sqrt{(M_{cvg}^{CPL} - MU)^2}^{Reg_{SST}} \quad (8)$$

These two indexes show the intensity of the moisture convergence change when only the wind field changes (IU) or when only the moisture field changes (IQ). Finally, these ratios are calculated:

$$U_{chg} = IU/I_M \quad (9)$$

$$Q_{chg} = IQ/I_M \quad (10)$$

The closer to 1 that these ratios are, the larger their contribution to changes in the moisture convergence field between CPL and CTL is. Table 7 shows that in all the regions and for both models, U_{chg} is close to 0.9 while Q_{chg} is closer to 0.20-0.30. This means that the changes in moisture convergence are clearly linked with wind changes in WRF and ALADIN models rather than to moisture changes in the lower atmosphere. From this, we can infer that the precipitation changes are most probably caused by wind changes than moisture changes in all the regions for WRF and ALADIN, which is consistent with the mechanisms identified in Berthou *et al.* (2015).

Table 8 further explains why the rain differences arise from wind changes rather than moisture changes. Near-surface relative humidity in the upstream region above the sea reaches values greater than 75%. This is in line with the 10 cases studied by Duffourg and Ducrocq (2011) in the Cévennes and is common to all the regions studied. The air is already almost saturated with moisture and the moisture fluxes occurring in this zone do not change the moisture content much. The wind changes are most probably linked with temperature changes.

Changes in surface heat fluxes.

We now investigate the surface heat fluxes in order to understand better the link between SST changes and precipitation changes. Table 9 shows the daily mean and standard deviation of surface heat fluxes for each zone. Even though the relative humidity is high (Table 8), latent heat fluxes are always larger than sensible heat fluxes by at least a factor of 3. The Cévennes and Northeastern Italy show the lowest mean sensible (less than 10 W m^{-2}) and latent heat fluxes

		Cévennes	Valencia	Calabria	Central Italy	Northeastern Italy
U_{chg}	WDCPL-WDCTL	0.86 (0.11)	0.95 (0.07)	0.92 (0.05)	0.96 (0.03)	0.86 (0.13)

Table 8. Mean 2m relative humidity (and standard deviation) (%) in the SST upstream zone (%)

(around 100 W m^{-2}) in the upstream regions. Calabria shows the largest mean sensible (43 W m^{-2}) and latent heat fluxes (207 W m^{-2}) followed by Valencia and Central Italy. Note that these fluxes are much weaker than heat fluxes occurring with the Mistral blowing from the continent over the ocean which can be larger than 500 W m^{-2} (Flamant 2003; Lebeaupin Brossier and Drobinski 2009). In order to assess the changes in surface heat flux, a similar index as the ones for precipitation and SST is calculated: the spatial RMSE of the mean daily heat fluxes between CPL and CTL on the one hand and between CPL and SMO on the other, called I_{LH} for the latent heat flux and I_{SH} for the sensible heat flux. Fig. 7 and Fig. 8 show the results. In both differences, between CPL and CTL and CPL and SMO, changes in latent heat fluxes dominate the response to IPSS with a slope between I_{LH} and IPSS about 4 times larger than between I_{SH} and IPSS in all cases. Table 10 shows the robust relationship between I_{LH} and IPSS (slopes are not as robust for I_{SH} , not shown), showing the presumable role of latent heat flux in the relationship between rain changes and SST changes. However, I_{SH} also show sensitivity to the IPSS and may also play a role.

Moreover, it shows that for Central Italy and Northeastern Italy, a robust relationship of the latent heat flux to the IPSS is also found whereas no robust relationship is found between i_{rain} and IPSS. These changes in the heat fluxes do not linearly impact the precipitation events over Central Italy and Northeastern Italy as discussed before.

The Cévennes show weaker fluxes and weaker sensitivity of fluxes to the IPSS, possibly leading to the weaker sensitivity of precipitation changes to IPSS compared to Valencia and Calabria. This different sensitivity could also be linked with different mechanisms linking SST changes with rain changes. Calabria and Spain show similar sensitivity of I_{LH} to the IPSS and of i_{rain} to the IPSS.

5. Quality and use of the IPSS without CPL-SMO simulations for the precipitation

5.1. IPSS in datasets based on observations

In the previous section, we investigated the effects of both CPL-CTL and CPL-SMO differences. The aim of examining the CPL-CTL difference was to investigate the effect of changes of SST that can be quite large (up to IPSS of 4.0°C for ALADIN and up to 2.1°C for WRF for single events) on precipitation. However, those differences are not easy to discuss physically since they arise from the monthly update of CTL SST for ALADIN, from the climate models biases that accumulate over the long term and also from the proper coupling effects of the atmosphere with the ocean. These simulations were useful in assessing the impact of relatively large changes of SST on heavy rain. However, the SMO simulations were computed to get physically relevant SST differences that do arise from the coupling of the atmosphere with the ocean at temporal scales smaller than a month. However, it is legitimate to wonder if variations of SST at submonthly time scales are realistic. Section 3 has shown a good ability of the models to represent the September to December climatological spatial distribution of submonthly variations of SST, though they tend to underestimate the intensity especially compared to the CNR dataset. The aim of this section is to check if the models are able to reproduce the submonthly variations of SST when HPEs occur. If it is the case, we can build an IPSS index with the observations in the regions of interest to evaluate when submonthly coupling can impact HPEs.

Two products of optimal interpolation, a global one (OSTIA SST) and a regional one (CNR SST), are used for the comparison with the models (section 2.3). The IPSS is calculated for each dataset in the same way that the IPSS for the CPL-SMO simulation is computed. First, the time series of SST is smoothed over a month

around the event date, as for SMO simulation.. Then, the IPSS is computed in this way:

$$IPSS_{dt} = \sqrt{(SST_{dt} - [SST_{dt}]^{mth})^2}^{Reg_{SST}} \quad (11)$$

where “dt” stands for OSTIA or CNR dataset and $[-]^{mth}$ shows the 31 day average centered on the day of the event. These “observed” IPSS can then be compared with the simulated IPSS. There is no SMO simulation for ALADIN but such IPSS can also be calculated in the way described by Eq. (11) from the ALADIN CPL SST. It is equivalent to the IPSS calculated between CPL and SMO simulations. Fig. 9 and Table 11 show the IPSS comparison.

The Cévennes upstream region shows good agreement in IPSS between both datasets and between WD and the datasets (Fig. 9a). Table 11 confirms the results, with high correlation coefficients for ALADIN (0.78-0.79), WR (0.77-0.84) and WD (0.75-0.84). Therefore, we can be more confident in the results for the Cévennes: WD and WR are able to reproduce quite well the variations of SST due to Mistral/Tramontane winds and to the recovery of the ocean mixed layer after such episodes in the Gulf of Lions and down to Sardinia.

In the upstream region of Valencia (i.e. the Balearic Sea), the agreement between CNR and OSTIA datasets is not as good with correlations of 0.65-0.75. The correlations between models and datasets are also of the same order. However, the correlations are still significant: we can conclude that the models are also able to represent submonthly variations linked to the Cierzo, Tramontane and Mistral or to Catalan eddies in this region, although the conclusion is not as strong as in the Cévennes upstream region.

The Calabria upstream region shows weaker variations in the model and in the datasets: most of the data is confined below $0.5^{\circ}C$ in Fig. 9c. The effects of the Gregale and Sirocco seem to be weaker on SST submonthly variations. However, we showed in the previous part that such variations were strong enough in this region to generate rain anomalies.

Table 11 shows that the correlation between CNR and OSTIA is not strong in this region (between 0.32 and 0.62 among the three sets of events). The models also agree less with the datasets. WDCPL shows better agreement with OSTIA while ALCPL agrees better with CNR. Fig. 9 shows that WDCPL tends to underestimate submonthly variations by 0.1 to $0.5^{\circ}C$ in the region compared to the datasets, with larger underestimation compared to CNR. It is hard to evaluate the submonthly variations of models with such disagreement among the datasets. However, these regions should deserve particular attention regarding the impact that SST has on HPEs in RCMs.

The IPSS in Central Italy is calculated either with the box in the Adriatic or in the Tyrrhenian sea depending on the direction of the incoming flow (Fig. 4). The models show reasonable agreement with the datasets. So do the datasets together.

The IPSS of Northeastern Italy computed over the Adriatic sea shows a weak agreement between OSTIA and CNR (0.10) for WD. The very strong Pearson correlation coefficient for WR is again given by one outlier with an IPSS of $1.9^{\circ}C$. Once removed, the correlation is very weak (below 0.16) between the datasets and between the model and each dataset. ALADIN shows better agreement but it is still not very conclusive. We can infer from these results that the submonthly variations of SST in the Adriatic sea are very variable among the datasets and the models, so that no proper agreement is reached, either between the datasets or between each model and each dataset. However, this is not critical for HPEs since they are weakly sensitive to those variations (Fig. 5e).

5.2. Which HyMeX SOP1 events were sensitive to submonthly air-sea coupling?

This article allowed us to identify three regions among the six HyMeX regions most hit during HyMeX SOP 1 that are sensitive to SST changes in the upstream region where the low-level jets feeding the event blow: the Cévennes, Valencia and Calabria. Now that a relationship has been built between I_{rain}/P_{max} and

Figure 7. Indexes of latent (I_{LH} , + crosses) and sensible (I_{SH} , x crosses) heat flux differences calculated for every event (one cross is one event) in the zone named above each panel and plotted against the IPSS in the corresponding SST zone for WDCPL-WDCTL (blue crosses) and WRCPL-WRCTL (red crosses). Each cross is one event as selected in Table 3.

IPSS, and now that this IPSS for submonthly variations of SST is comparable between different datasets, we can use both WRCPL and ALCPL simulations together with CNR and OSTIA optimal interpolation products to give an estimation of the IPSS due to submonthly

variations and an estimation of which HyMeX events may have been affected by these variations. For the three zones under consideration, Table 12 presents the events during HyMeX SOP 1 for which recorded daily precipitation exceeded 100 mm in the selection zones

Figure 8. Same as Fig. 7 for WDCPL-WDSMO and WRCPL-WRSO. Note the The scale is different.

defined in Fig. 2 (the rain gauge maximum is given for each date). The associated IPSS for each simulation or dataset is given. Using Fig. 6, an estimation of the relative i_{rain} , is given for the minimum, mean and maximum of the four IPSS. The I_{rain}/P_{max} WRCPL-WRSO, using the modeled P_{max} is also given when

the original grid rain maximum in the model is larger than 30 mm.

The results show that the events with large submonthly deviations of SST from the moving monthly average, which may modulate them, were 25 and 26 October in the Cévennes with statistical i_{rain} of

Figure 9. IPSS computed for WRCPL-WRSO plotted against the IPSS calculated for the two datasets (blue + crosses: OSTIA dataset, green x crosses: CNR dataset, the black line in between links the same events). Each cross is one event as selected in Table 3. The black line is the unity line.

about 0.04 to 0.05 and 28 September and 12 October for Valencia with estimated values of 0.05 and 0.07. WRCPL-WRSO is within the estimated range for

most events and gives a larger i_{rain} for Calabria of about 0.07, which indicate that the event was more sensitive to the SST changes than the average in

Table 12. IPSS of the submonthly SST variations for the Hymex SOP1 events (Ducrocq *et al.* 2014) with cumulated rain larger than 100 mm in raingauges for models and datasets; estimated relative i_{rain} (minimum, mean, maximum) using the relationship in Fig. 5 and the minimum, mean and maximum IPSS from datasets and models; i_{rain} for the only available set of CPL-SMO simulations: WRCPL-WRSMO when maximum daily precipitation in the model is larger than 30 mm (and precipitation maximum).

this model. As shown in Fig. 3, 25 and 26 October (IOP 16a) are just followed by a very strong Mistral event from 27 to 30 October (IOP 16b), as studied by Lebeaupin Brossier *et al.* (2014), which makes the situation of the HPE in a peak of submonthly variations. The event of the 18 October is preceded by a weaker but longer Mistral event, which makes the submonthly variations not as strong on the event day. The 28 September in Valencia is preceded and followed by SST cooling in the Balearic sea linked with southeasterly and northeasterly winds while the 12 October is followed by strong northerly winds (not shown).

6. Discussion and conclusion

This study uses regional climate modeling to address the question of where extreme precipitation events are sensitive to sea surface temperature changes in direct upstream regions either caused by model biases or by air-sea submonthly coupling. This submonthly air-sea coupling is mostly linked with local strong wind regimes, their effect on the ocean dynamics and the SST and the corresponding atmospheric response. Regions where intense precipitation events occurred

during HyMeX SOP1 (autumn 2012) were selected for the study: Valencia in Spain, the Cévennes in Southern France, Liguria in Northwestern Italy, Central Italy, Calabria and Northeastern Italy. The 30 most extreme events in hindcast simulations of a period of 20 to 24 years were selected for two models: the MORCE platform in two configurations (WR and WD, 20 km resolution) and the CNRM-RSCM4 (ALADIN, 50 km resolution).

Liguria was the only region excluded from the study since less than 25% of the observed events were represented by the models while this score was between 40 and 50% in the other regions where good quality gridded rain datasets were available, i.e. Valencia, the Cévennes and Northeastern Italy. For these zones, between 70 and 90% of the modeled extreme events were in the 100 largest observed events, which means that the selected events are HPEs, even if not all of them are extreme in reality. Even though Central Italy and Calabria did not show good hit rates, both regions were kept for the study since the E-OBS dataset used for these regions showed limited skills to evaluate the models. Though regional climate modeling does not capture events triggered

or enhanced by subgrid mechanisms (cold pools, fine-scale topography interactions...) but rather the large-scale forced events (linked to surface fronts and low-level convergence zones, interactions with large-scale orography, tropospheric divergence, ...), it allows statistical studies of sensitivity to the changes in SST on this later sort of heavy precipitation events.

With the use of synthetic indexes (I_{rain} and IPSS), this study statistically shows that changes in extreme precipitation events represented by RCMs are linearly related to SST changes in the upstream zone that covers most of the low-level jets upstream of HPEs in three regions: the Cévennes in Southern France, Valencia in Spain and Calabria in Italy. This result is robust in both models. Changes in the convergence of moisture in the systems are linked with changes in low-level dynamics rather than in low-level specific humidity in both models. Changes in surface heat flux are responsible for the temperature changes at the origin of wind changes. The Cévennes shows a weaker sensitivity to SST compared to Spain and Calabria. Central Italy showed no convincing relationship between upstream SST differences and rain differences. However, heat flux differences showed a similar relationship with IPSS as in the other regions. Northeastern Italy showed weak sensitivity to SST changes except for a few events, presumably due to the narrow configuration of the Adriatic Sea and the dependency on the trajectory of the low-level jet (along or across the Adriatic sea).

Moreover, in the Cévennes, Valencia and Calabria, precipitation can be modulated by submonthly variations of SST (with an I_{rain}/P_{max} larger than 0.05). This means variations due to strong wind regimes or oceanic circulation. Valencia shows the largest modulation by these variations while Calabria shows the same sensitivity but weaker SST submonthly variations. However, the IPSS in the models is underestimated by about 0.1°C in this region. The Cévennes region has a weaker sensitivity but IPSS as strong as in Valencia. On the contrary, no significant effect of submonthly coupling on HPEs has been found for Northeastern Italy and a more random relation is found for Central Italy. Both situations (strong continental wind regimes and HPEs) happen separately but oceanic response can link them (Lebeaupin Brossier et al. (2013); Berthou et al. (2014) for the Cévennes). The synoptic link between strong wind regimes cooling the SST and HPEs is not investigated in this study and it is assumed that both types of events can happen independently. However, future work will study such links in Valencia where $SST_{CPL} - SST_{SMO}$ are predominantly negative (in 73% of the cases) while it is more equilibrated for the Cévennes (50%) and Calabria (60%).

The submonthly variations of SST in the models were then compared with the submonthly variations in high-resolution optimally-interpolated SST product in order to further validate the results. The models represent well the variations in the upstream region of the Cévennes, Valencia and Central Italy, where both datasets used for validation also agree with each other. In Calabria and Northeastern Italy, the two datasets OSTIA and CNR do not agree well: some of the model versions show some agreement with CNR, others with

OSTIA but there is no clear agreement. Therefore, further work needs to be undertaken on these regions for the improvement of datasets and models in terms of submonthly variations of SST (representation of winds and of the ocean circulation at submonthly time-scales), especially upstream of Calabria regarding the importance of SST variations in the modulation of the HPEs in this region.

Finally, submonthly variations of SST that occurred during the HyMeX events were calculated for both models and both datasets in order to know whether or not some rain events may have been influenced by such variations coming from air-sea coupling. Datasets and models provided a range of IPSS and the use of the above-mentioned relationships between IPSS and i_{rain} gave a range of relative i_{rain} . It indicates that the events of 25 and 26 October in the Cévennes the 28 September and 12 October in Valencia were most probably modulated by variations in SST that occurred within 15 days of the event.

A first limit of our study is the use of only two AORCMs, which while very different were both shown to calculate excessively strong surface fluxes (Di Luca et al. 2014; Sevault et al. 2014). Further tests could be done with remote areas. Another limit is the lack of representation of fine-scale processes triggering and enhancing heavy rain events that are better represented in numerical weather prediction models at the scale of a few kilometers. We considered only 30 events so that 70 to 90% of them are in the 100 heaviest events of the datasets: we analysed HPEs represented by RCMs and missed the ones enhanced or triggered by subgrid mechanisms. This was a trade-off between representing both the atmosphere-ocean coupling and the HPEs in long simulations with an AORCM while keeping reasonable computational costs. This work should therefore be considered as a first approach. To keep the advantage of regional climate modeling as the possibility to look for statistical relationships on sensitivity experiments, regional climate convection permitting models with 1-4 km grid spacing are an interesting perspective (Kendon et al. 2014; Prein et al. 2015b). Further work is needed in order to understand specifically in each region the mechanisms at play linking low-level temperature differences arising from SST differences to rain differences through low-level wind changes but this is beyond the scope of the present study. Further work is also needed in the Eastern Mediterranean basin where strong air-sea interactions also occur at submonthly time-scales (e.g. the Etesians in Greece) and heavy precipitation events are also at play.
