Highlights

We present new geochronology data from the southwestern part of the Rhodope

The study area (Chalkidiki block) retains a rather rich Cretaceous isotopic record

Monazite breakdown at ~132Ma provides a minimum age for the amphibolite-facies event

Amphibolite-facies overprint predates the end of thrusting in the area

Cooling and arrival at shallow crustal levels occurred by the end of Early Cretaceous

ABSTRACT

The Chalkidiki block is a major domain in the North Aegean that, contrary to other domains in the region, largely escaped thermal perturbations during Tertiary extension. As a result, the Chalkidiki block is an ideal candidate to glean information related to the timing of Mesozoic thermal events using appropriate geochronological techniques. We have undertaken a laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS) study (U-Th-Pb on monazites and U-Pb on zircons) coupled with $^{40}\text{Ar}/^{39}\text{Ar}$ dating on nine samples from various structural levels within the thrust system of the Chalkidiki block. The eastern, and structurally lower part of the system revealed a complete isotopic reset of Carboniferous – Early Triassic monazites coeval with partial monazite destruction, REE-mobilisation and formation of apatite-allanite-epidote coronas at ~132 Ma, a reaction that is commonly observed in amphibolite-facies rocks. These coronas formed after crystallisation of garnet (i.e., at $T > 580^\circ\text{C}$) and, in all probability, either close to the peak-temperature conditions (~620°C) on a prograde path or during retrogression between the peak-temperature and the low-temperature boundary of the amphibolite facies. Cooling of these rocks and arrival at mid-crustal levels occurred at 95-100 Ma. By contrast, the western, and structurally uppermost part of the system went through the same event by 120-125 Ma. Further structural considerations with respect to medium-temperature geochronology data imply that syn-metamorphic thrusting must have ceased by early Late Cretaceous. We emphasize that, with the sole exception of the Chalkidiki block, no pre-45 Ma medium-temperature geochronology data are preserved in other North Aegean domains, a feature that is clearly related to the extension-induced thermal perturbation of the region during the Tertiary.

Keywords: Aegean, Rhodope, monazite, micas, Ar/Ar, U-Th-Pb

1. Introduction

The Hellenic Thrust Wedge resulted from the Mesozoic to Early Cenozoic Eurasia-Africa convergence manifested by (i) the southward-verging accretion of three continental blocks (van Hinsbergen et al., 2005), namely, from top to base, the Rhodopia, Pelagonia and the External Hellenides, and (ii) the closure of two intervening oceanic domains along the two suture zones of Vardar-Axios and Pindos (Robertson, 2002; Papanikolaou, 2009; 2013) (Fig.1). Extensional inversion of the Hellenic Thrust Wedge that initiated in Early Cenozoic corresponds to gravity spreading with a rate controlled by the velocity of the trench retreat (Gautier et al., 1999; Jolivet and Faccenna, 2000; Brun and Sokoutis, 2010; Jolivet and Brun, 2010; Kydonakis et al., 2015a; Brun et al., 2016).

The Mesozoic convergence history has received significant attention leading to regional considerations for the hinterland of the Hellenic Thrust Wedge collectively known as the Rhodope (Burg et al., 1990; 1996; Ricou et al., 1998). Following the discussion in Kydonakis et al. (2015a), the Rhodope can be divided into three distinct domains that are, from northeast to southwest, the Northern Rhodope Domain, the Southern Rhodope Core Complex and the Chalkidiki block (Fig.2). The Northern Rhodope Domain and the Chalkidiki block arguably participated in the same Mesozoic metamorphic event(s) experiencing, however, different tectono-thermal histories whereas the Southern Rhodope Core Complex (and the time-equivalent Northern Rhodope Core Complex) developed exclusively during the Middle Eocene-Miocene Aegean extension (see Kydonakis et al., 2015b and discussion therein).

The exact timing of these metamorphic event(s) in the north Rhodope is often accessed by geochronology studies (e.g., Reischmann and Kostopoulos, 2002; Liati et al., 2011) the results of which are commonly tested against regional structural analysis (e.g., Ricou et al., 1998; Krenn et al., 2010). Although the peak eclogite-facies metamorphic event is generally accepted as being Jurassic in age, with some controversy involved (see Burg et al., 2012; and references therein), the post-peak thermal history is not explicitly constrained with respect to the Mesozoic cooling. This is likely due to (i) extensive reworking during the Cenozoic extension coeval with gneiss domes formation, widespread igneous activity and the related high thermal gradient and (ii) absence of application of medium-temperature geochronology methods on non-affected lithologies within appropriate domains. In fact, medium-temperature geochronology data ($^{40}\text{Ar}/^{39}\text{Ar}$ on micas) point mostly toward an Eocene - Miocene age which can be only linked to the Tertiary extension (e.g., Lips et al., 2000; Bonev et al., 2013). The Chalkidiki block, the southern domain of the Rhodope, largely escaped the thermal effects of the Tertiary extension and, therefore, constitute an ideal candidate to define the Mesozoic post-peak metamorphic evolution in the North Aegean.

In this contribution we present new $^{40}\text{Ar}/^{39}\text{Ar}$ (micas) and LA-ICP-MS (monazite and zircon) ages from the Chalkidiki block. Our results are analysed and interpreted under three complementary perspectives: (i) the timing of the regional amphibolite-facies metamorphism as well as the post-peak thermal cooling, (ii) the end of syn-metamorphic thrusting and (iii) the significance of tectonic/metamorphic events recorded at the scale of the Rhodope Metamorphic Province.

2. Geological setting

2.1 The Rhodope Metamorphic Province

The Rhodope Metamorphic Province, or simply the Rhodope, constitutes the hinterland of the Hellenides (northeast Greece - southwest Bulgaria) and is considered an area of large-scale nappe tectonics that recorded the Mesozoic convergence-related deformation of the Aegean (e.g., Burg et al., 1990; 1996; Ricou et al., 1998; Krenn et al., 2010; Jahn-Awe et al., 2010; Nagel et al., 2011; Burg, 2012; and references therein) (Fig.2). The Rhodope can be described as a Mesozoic southwestward verging crustal-scale pile of syn-metamorphic thrust units (Burg et al., 1996; Ricou et al., 1998) strongly affected by Cenozoic extension of core complex type (Dinter and Royden, 1993; Sokoutis et al., 1993; Bonev et al., 2006; Brun and Sokoutis, 2007) and syn- to post-extension magmatism (e.g., Kolocotroni and Dixon, 1991; Jones et al., 1992; Marchev et al., 2004, 2013). It is bordered to the north by the Maritza dextral strike-slip fault, to the east by the Middle Eocene to Quaternary Thrace Basin, to the west by the Vardar-Axios - Thermaikos basin that roughly correlate with the Vardar Suture Zone and to the south by the North Aegean Trough. Following Kydonakis et al. (2015a), we recognise three major domains in the Rhodope that are, from northeast to southwest: (i) the Northern Rhodope Domain, (ii) the Northern and Southern Rhodope Core Complexes, and (iii) the Chalkidiki block (Fig.2).

The Northern Rhodope Domain (NRD) is the northeastern part of the Rhodope and represents an imbricate system mostly made of high-grade metamorphic rocks including a former Upper Jurassic magmatic arc (Fig.2). Orthogneisses, mafic eclogites and amphibolites, paragneisses, scarce marble horizons and ultramafics appear within the NRD (e.g., Mposkos and Liati, 1993; Liati and Seidel, 1996; Turpaud and Reischmann, 2010; Janák et al., 2011).

Although upper amphibolite-facies metamorphic rocks are widespread, many occurrences of variably retrogressed eclogites that preserve evidence of an older high-pressure (HP) phase have been reported (e.g., Burg, 2012; Moulas et al., 2013 and references therein). Micro-diamond inclusions in metapelites attest for the existence of an ultrahigh-pressure (UHP) event that indicates a minimum local pressure of 3.0 GPa (for 600 °C) (Mposkos and Kostopoulos, 2001; Perraki et al., 2006; Schmidt et al., 2010). Jurassic and Cretaceous zircon/monazite metamorphic ages from both garnet-kyanite gneisses and amphibolitised eclogites have been reported in the literature (Reischmann and Kostopoulos, 2002; Bauer et al., 2007; Hoinkes et al., 2008; Bosse et al., 2010; Krenn et al., 2010; Liati et al., 2011; Didier et al., 2014). Metamorphic conditions are estimated at 1.9 GPa / 700 °C for the HP event recorded in mafic rocks and at 0.7 GPa / 720 °C for the regional amphibolite-facies overprint (Liati and Seidel, 1996; Moulas et al., 2013). Metapelite assemblages record higher pressure for the high-temperature overprint (1.2-1.3 GPa / 700-730 °C; Krenn et al., 2010). To the northeast, Maastrichtian - Ypresian deposits (Boyanov et al., 1982; Goranov and Atanasov, 1992) rest with fault contacts on basement gneisses (Bonev et al., 2006) and partly overlap, in age, with Latest Cretaceous-Earliest Oligocene plutonic rocks and volcanics (e.g., Peytcheva et al., 1998; Soldatos et al., 2001; 2008; Ovtcharova et al., 2003; Marchev et al., 2006, 2010; Jahn-Awe et al., 2010; Filipov and Marchev, 2011).

The Southern Rhodope Core Complex (SRCC) is a wide metamorphic dome of roughly triangular shape that shows a flat-lying foliation over its width and lies immediately southwest of the NRD (Brun and Sokoutis, 2007) (Fig.2). The contact between the SRCC and the NRD is located along a mylonite-bearing syn-metamorphic SW-verging thrust fault known as the Nestos Thrust (e.g., Papanikolaou and Panagopoulos, 1981; Gerdjikov and Milev, 2005). The SRCC consists of highly deformed Permian-Carboniferous mylonitic orthogneisses, micaschists and

amphibolites capped by a thick marble sequence (e.g., Kronberg et al., 1970; Turpaud and Reischmann, 2010). The gneisses reached upper greenschist/lower amphibolite-facies conditions and the available metamorphic ages are post-Early Eocene (i.e., post-51 Ma) (Wawrzenitz and Krohe, 1998; Lips et al., 2000). Oligo-Miocene plutonic bodies that show syn-tectonic fabrics intruded the basement rocks (Kolocotroni and Dixon, 1991; Kaufman, 1995; Dinter et al., 1995; Eleftheriadis et al., 2001). Widespread NW-SE-trending basins were developed after Middle Miocene (e.g., Snel et al., 2006).

Gravity spreading of the thickened Hellenic crust during the Early Cenozoic extension led to the exhumation of the SRCC that separated the NRD, to the northeast, from the Chalkidiki block to the southwest (Fig.2; see also fig.4 in Kydonakis et al., 2015a). Exhumation was controlled by the Kerdyllion Detachment whose hanging-wall is the Chalkidiki block (Brun and Sokoutis, 2007). In the course of exhumation, the Chalkidiki block (i) behaved as a coherent block that rotated 30° clockwise during the Paleogene and was only affected by moderate internal deformation, (ii) underwent moderate brittle north-south extension since the Middle Miocene and (iii) was only locally intruded by magmatic bodies during the Tertiary (Kondopoulou and Westphal, 1986; Brun and Sokoutis, 2004; 2007). The tectono-thermal history of the Chalkidiki block created rather favourable conditions for maintaining isotopic evidence of the cooling path after peak metamorphic conditions.

2.2 The south-western part of the Rhodope: the Chalkidiki block

A number of south-westward verging thrusts separated by sharp NW-trending contacts define the Chalkidiki block. For the purpose of this study we will investigate the two easternmost

units that are the Vertiskos Unit, to the east, and the Circum-Rhodope belt, to the west (Kockel et al., 1971; 1977; Kauffmann et al., 1976; Kockel and Mollat, 1977) (Fig.3).

The Vertiskos Unit is an elongated NW-trending basement belt with complex tectono-metamorphic history (Fig.3). It is made of Silurian - Ordovician granitoids (later transformed into orthogneisses), paragneisses, thin marble horizons, leucocratic granitic/pegmatitic intrusions, deformed amphibolites, scarce eclogite boudins and serpentinites (Kockel et al., 1971, 1977; Himmerkus et al., 2009a). The Arnea-Kerkini Magmatic Complex intruded the Vertiskos Unit during the Early Triassic (Himmerkus et al., 2009b) and both, as a coherent basement complex, experienced the same post-intrusion metamorphic overprint(s) (Burg et al., 1995; Kiliyas et al., 1999). Metamorphic K-Ar ages range between 140 and 90 Ma (e.g., Borsi et al., 1965; Harre et al., 1968; Marakis, 1969; Papadopoulos and Kiliyas, 1985; Christofides et al., 1999) (Fig.4). Rubidium/strontium metamorphic ages show intense dispersion and a number of non-reset Permian - Jurassic ages but the youngest age cluster correlates well with the Cretaceous K-Ar metamorphic ages (e.g., Zervas et al., 1979; Papadopoulos and Kiliyas, 1985; de Wet et al., 1989) (Fig.4). Lips et al. (2000) reported a 143 ± 5 Ma $^{40}\text{Ar}/^{39}\text{Ar}$ age (white mica; plateau age) from a quartz-calcite mylonite and de Wet et al. (1989) a 136 ± 1 Ma (biotite; plateau age) from the Arnea Magmatic Complex (Fig.4).

The Circum-Rhodope belt is a Triassic - Jurassic meta-sedimentary sequence locally involving Triassic rhyolites and quartzites at the base (Kauffmann et al., 1976; Asvesta and Dimitriadis, 2010; Meinhold and Kostopoulos, 2013) (Fig.3). It is largely made of phyllites, schists and carbonates and is considered as the Mesozoic sedimentary cover of the Vertiskos Unit (Kockel et al., 1971; Kauffmann et al., 1976; Dixon and Dimitriadis, 1984). Outliers of the Mesozoic Circum-Rhodope belt lie directly on top of the Vertiskos Unit toward the east (Fig.3).

Part of these outliers were indeed originally mapped as part of the Circum-Rhodope belt (Kockel et al., 1977; see also Dixon and Dimitriadis, 1984) but re-interpreted later as individual units under various local names such as the “Nea Madytos Unit” of Sakellariou and Dürr (1993) or the “Bunte Serie” of Papadopoulos and Kiliadis (1985). This basement-cover complex lies beneath a thin basement fragment through a sharp NW-trending thrust contact (Kydonakis et al., 2015b) (Fig.3). For convenience, the terms “upper basement slice” and “lower basement-cover complex” will be used hereafter for the hanging-wall and foot-wall of the thrust contact, respectively. Basal rhyolites of the Circum-Rhodope belt yield Early Cretaceous (~120 Ma) K-Ar metamorphic ages (Bertrand et al., 1994) (Fig.4).

Evidence of a HP event from the Chalkidiki block is found in Asvesta (1992) who reported high-Si phengite from the base of the Circum-Rhodope belt and Michard et al. (1994) who reported the existence of high-Si phengite (3.52 atoms per formula unit - apfu) from basal rhyolitic meta-tuffs. Michard et al. (1994) estimated peak metamorphic conditions at circa 0.8 GPa / 350 °C for the HP event to the west. Thermodynamic bulk-rock considerations allowed more precise P-T estimations: (i) to the east, peak eclogite-facies conditions at 1.9 GPa / 520 °C and amphibolite-facies re-equilibration at 1.2 GPa / 620 °C and (ii) to the west, a pressure of up to 1.4-1.5 GPa may have been reached during the HP event (Kydonakis et al., 2015c).

3. Analytical methods

3.1 $^{40}\text{Ar}/^{39}\text{Ar}$ step heating method

Fresh samples of phyllites, gneisses and mica-schists were selected for step-heating laser probe $^{40}\text{Ar}/^{39}\text{Ar}$ dating. The samples were crushed, sieved prior to handpicking (single mica grains) under binocular microscope and cleaning in ultrasonic bath using acetone and distilled water. Biotites and white micas were packaged in aluminium foils and irradiated in the core of the Triga Mark II nuclear reactor of Pavia (Italia) with several aliquots of the Fish Canyon sanidine standard (28.03 ± 0.08 Ma) (Jourdan and Renne, 2007) as flux monitor. Argon isotopic interferences on K and Ca were determined by irradiation of KF and CaF_2 pure salts from which the following correction factors were obtained: $(^{40}\text{Ar}/^{39}\text{Ar})_{\text{K}} = 0.00969 \pm 0.00038$, $(^{38}\text{Ar}/^{39}\text{Ar})_{\text{K}} = 0.01297 \pm 0.00045$, $(^{39}\text{Ar}/^{37}\text{Ar})_{\text{Ca}} = 0.0007474 \pm 0.000021$ and $(^{36}\text{Ar}/^{37}\text{Ar})_{\text{Ca}} = 0.000288 \pm 0.000016$. Argon analyses were performed at Géosciences Montpellier (France) with an analytical system that consists of: (a) an IR- CO_2 laser of 100 kHz used at 5-15% during 60 sec, (b) a system of lenses for beam focusing, (c) a steel chamber, maintained at 10^{-8} - 10^{-9} bar, with a drilled copper plate and the four samples on, (d) an inlet line for purification of gases including two Zr-Al getters, (e) a multi-collector mass spectrometer (Argus VI from Thermo-Fisher). A custom-made software controls the laser intensity, the timing of extraction/purification and the data acquisition. To measure the argon background within the system, one blank analysis was performed every three sample analyses. The ArArCalc software© v2.5.2 was used for data reduction and plotting. One-sigma errors reported for plateau, isochron and total gas ages include the error on the irradiation factor J. Atmospheric ^{40}Ar was estimated using a value of the initial $^{40}\text{Ar}/^{36}\text{Ar}$ of 295.5.

3.2 LA-ICP-MS U-Th-Pb monazite and U-Pb zircon dating

Monazite grains were imaged *in-context* on well-polished thin sections by back-scattering imaging using a JEOL JSM-7100F field-emission scanning electron microscope operating at an accelerating voltage of 20 kV available at Université de Rennes 1, France. For zircon grains, a classic separation procedure was followed at the facilities available at Géosciences Rennes, France. The samples were crushed and the zircon grains were separated using a Wilfley table, heavy liquids and a Frantz isodynamic separator before being handpicked under a binocular microscope and embedded in one-inch thick epoxy pucks. Zircon grains were imaged by cathodoluminescence (CL) using a Reliotron CL facility at Géosciences Rennes. LA-ICP-MS isotopic measurements were conducted for both monazite and zircon grains using an ESI NWR193UC Excimer Laser coupled to a quadrupole Agilent 7700x ICP-MS at Géosciences Rennes, France. For a complete account of the analytical procedures see Ballouard et al. (2015). Ablation spot diameters of 7 μm for monazite or 26 μm for zircon with repetition rate of 3 Hz and laser intensity of 7.5 J/cm² were used throughout. The data were corrected for U-Pb and Th-Pb fractionation and for mass bias by standard bracketing with repeated measurements of international standards. For monazite dating, the Moacyr monazite standard (Gasquet et al., 2010) was used. At regular intervals, the Manangoutry monazite (555 ± 2 Ma; Paquette and Tiepolo, 2007) was used as unknown to ensure quality control of the isotopic measurements (556.2 ± 2.6 Ma; MSWD = 0.44; N = 12). For zircon dating, the GJ-1 zircon standard (Jackson et al., 2004) was used whereas the 91500 zircon standard (1065.4 ± 0.6 Ma; Wiedenbeck et al., 1995) was treated as unknown to ensure quality control (1062 ± 3 Ma; MSWD = 0.098; N = 12). Data reduction was carried out using the GLITTER® software package developed by Macquarie Research Ltd. (Jackson et al., 2004). Concordia ages and diagrams were generated using Isoplot/Ex (Ludwig, 2001) updated to ver. 2.45/4.15.

3.3 Electron microprobe analyses

Mineral analyses were obtained at ETH Zurich, Switzerland and National Technical University of Athens, Greece using a JEOL JXA-8200 and a JEOL JSM-6380 low vacuum scanning electron microscope both operating at an accelerating voltage of 15 kV, 2 μm beam diameter and 20 nA beam current.

4. Strategy and samples description

Nine samples were selected for $^{40}\text{Ar}/^{39}\text{Ar}$ step heating, U-Th-Pb and U-Pb dating on micas, monazite and zircon, respectively (Table 1). The sampling locations are shown in Fig.3. Five samples belong to the lower basement-cover complex: two samples are from the western part (CR4 and CR10) and another three from the east (SM15, SM40, SM56). With the exception of SM15 for which a protolith age cannot be inferred based on stratigraphic criteria, the remaining samples belong to the Mesozoic sedimentary sequences of the area. Four additional samples belong to the upper basement slice: two samples are from paragneisses of unknown protolith age embedded in the basement (SM24 and SM42) and another two from the Triassic Arnea Magmatic Complex (SM9 and SM78). An overview of the micas and monazite chemistry is given in Fig.5 and Fig.6, respectively. Representative micas and monazite analyses can be found in Table 2 and Table 3, respectively.

4.1 Phyllites/schists from the lower basement-cover complex

Sample CR4 is a fine-grained quartz-mica phyllite. In the field it has a dominant foliation and a prominent NW-trending crenulation lineation. The main mineral phases are, in decreasing modal amount, quartz, white mica, chlorite, garnet and opaque minerals. A typical crenulation cleavage is developed by differentiation at the limbs of microlithon domains. The microlithons are dominated by quartz and kinked, often chloritised, medium-grained white micas. The cleavage domains are made of fine-grained K-rich white micas or a fine-grained aggregate composed of K-rich white mica, paragonite and chlorite. The Si content of the K-rich mica from the matrix ranges from 3.1 to 3.25 anion per formula unit (apfu) and contains up to 2.4 wt.% Na₂O. Paragonite from the matrix has a Na/(Na + K) ratio around 0.9 apfu and contains small amounts of Ca (less than 0.1 apfu). No systematic chemical variation between the large (microlithon domains) and the smaller (crenulation domains) mica grains was observed. Garnet (typically 2-3 mm in diameter) appears heavily replaced by chlorite and is only preserved as small patches within the chlorite mass. Garnet composition varies between Alm₆₇Grs₂₃Sps₆Pyr₄ and Alm₆₀Grs₂₅Sps₁₂Pyr₃. Despite the chlorite alteration, syn-tectonic features are still preserved. Quartz in the microlithon domains has healing features and is recrystallised with sharp grain boundaries and virtually no undulose extinction. Representative back-scattered images are given in Kydonakis et al. (2015c; fig.2).

Sample CR10 is a fine-grained phyllite with a dominant NW-trending crenulation lineation. Main phases are quartz, phengitic white mica and subordinate chlorite. The bedding can potentially be recognised as the interface between quartz- and white mica-rich layers. An anastomosing network of crenulation cleavage is defined by fine-grained white micas. Chlorite occasionally replaces the white mica. Phengite contains up to 3.31 apfu Si and also small amounts of Na (typically less than 0.4 wt.%).

Sample SM15 is a medium-grained garnet-kyanite micaschist. It appears in a relatively small isolated outcrop to the east and is intercalated with orthogneisses and highly-deformed amphibolites. It contains quartz, garnet, kyanite, white mica and rutile as the main phases and staurolite, chlorite, biotite (only as inclusion), ilmenite, epidote, phosphates, zircon and opaques as accessory phases. In the field it displays shear bands and rounded garnet/kyanite porphyroclasts surrounded by medium-grained matrix made of K-rich white mica. The K-rich white mica has Si content up to 3.36 apfu, contains up to 1.92 wt.% Na (~0.24 apfu) and is sometimes chloritised especially near the garnet rim. Garnet appears mostly anhedral, range from 500 μm to 3 mm in diameter and shows a weak zoning in major elements with almost flat spessartine/grossular components, increasing almandine and decreasing pyrope components toward the rim. Its composition ranges from $\text{Alm}_{64}\text{Grs}_5\text{Sps}_5\text{Pyr}_{26}$ to $\text{Alm}_{73}\text{Grs}_5\text{Sps}_5\text{Pyr}_{17}$ from core to rim. Monazite appears mostly in the matrix, often surrounded by a reaction corona, in relation with apatite; monazite inclusion in garnet also exists.

Sample SM40 is a garnet-staurolite micaschist from the eastern part of the area. Major phases are white mica, quartz, garnet, chlorite, staurolite and sub-ordinate kyanite. Accessory minerals are monazite, zircon and rarely ilmenite and allanite. The matrix is made of phengite, paragonite, rutile and quartz. Potassium-rich white mica is dominant in the matrix and contains up to 3.25 apfu Si and up to 0.24 apfu Na. Paragonite is less abundant with Na/(Na+K) ratio up to 0.9 and contains less than 1 wt.% Ca (<0.04 apfu). Garnet appears as euhedral to subhedral grains measuring up to 1.5 cm in diameter and contains white mica, rutile, ilmenite, chlorite, rare pyrite and an impressive amount of tourmaline as aligned inclusions. It displays zoning in major elements with $\text{Alm}_{65}\text{Grs}_{20}\text{Sps}_{11}\text{Pyr}_4$ cores and $\text{Alm}_{80}\text{Grs}_9\text{Sps}_0\text{Pyr}_{11}$ rims. Shear bands and

macroscopically visible spiral garnet indicate a top-to-the SW shear in hand specimen. Both garnet and staurolite preserve syn-tectonic features.

Sample SM56, although similar to SM40, it is more quartz-rich and its matrix is more fine-grained as a result of deformation. In thin section, garnet porphyroclasts measure up to 0.3 cm in diameter and show consumption textures. Staurolite can barely be recognised in thin sections and is often replaced by shimmer. This sample has suffered grain size reduction compared to SM40 possibly during retrogression.

4.2 Paragneisses and orthogneisses from the upper basement slice

4.2.1 Paragneisses of unknown protolith age embedded in the basement

Sample SM42 is a medium-grained garnet-bearing micaschist cropping out at the central-north part of the study area. It has a pronounced foliation and SW-directed shear indicators. It contains small garnet porphyroblasts (typically less than 2mm) surrounded by matrix made of K-rich white mica, biotite, quartz, ilmenite and subordinate plagioclase. Chlorite, phosphates, zircon and rutile appear as accessory minerals. The foliation is made by biotite and white micas. Biotite, although commonly found along the foliation plane, appears with anhedral grains which look like re-oriented porphyroclasts rather than growing in equilibrium with the white micas from the foliation. According to their textural position and size, two types of white micas are found: (i) big mica flakes, commonly at high angle to the foliation, and (ii) medium- to fine-grained micas found along the foliation plane. The latter white micas have Si content of up to

3.29 (apfu) and contain less than 1.3 wt.% Na. Garnet is up to 2 mm in diameter and shows a pronounced prograde zoning in major elements with decreasing spessartine/grossular and increasing almandine/pyrope components. Its composition range from $\text{Alm}_{57}\text{Grs}_{28}\text{Sps}_{12}\text{Pyr}_3$ to $\text{Alm}_{79}\text{Grs}_{10}\text{Sps}_1\text{Pyr}_{10}$ from core to rim.

Sample SM24 is a medium-grained garnet-kyanite micaschist also from the central-north part of the study area. It displays eye-shaped aggregates of garnet, biotite and kyanite surrounded by fine-grained matrix made mostly of K-rich white micas and quartz. Accessory minerals are ilmenite, zircon, phosphates and opaques. White micas from the matrix have a phengitic composition (up to 3.26 apfu). Garnet is typically around 2 mm in diameter (few bigger grains with 5 mm diameter were also found). Garnet shows a rather flat major element composition with almandine/pyrope dominating over the spessartine/grossular components and typical composition of $\text{Alm}_{75}\text{Grs}_{15}\text{Sps}_7\text{Pyr}_3$. Monazite appears in the matrix or as inclusion in the garnet and displays patchy zoning.

4.2.2 Orthogneisses of the Triassic Arnea Magmatic Complex

Samples SM9 and SM78 are both leucocratic orthogneisses from the Triassic Arnea Magmatic Complex. They contain K-feldspar, quartz, K-rich white mica, plagioclase and subordinate biotite as major mineral phases and zircon, rutile, apatite as accessory minerals. Despite the metamorphic overprint, both samples have preserved magmatic textures (such as myrmekites). Potassium-rich white micas are metamorphic in origin. For both samples, K-rich white mica from the foliation have up to 3.27 apfu Si content and contain negligible amount of Na.

5. Results

5.1 $^{40}\text{Ar}/^{39}\text{Ar}$ step heating results

Eight samples were used for $^{40}\text{Ar}/^{39}\text{Ar}$ micas dating. Degassing data and age spectra plots are shown in Appendix A.1 and Fig.7, respectively. A synopsis of the $^{40}\text{Ar}/^{39}\text{Ar}$ ages is given in Table 4. For the white mica we adopt a closure temperature of 420 ± 30 °C according to Harrison et al. (2009). This has to be considered as a minimum value since the closure temperature increases with the Mg/Fe ratio in phengite as well as with the grain size and the cooling rate (Agard et al., 2002; Augier et al., 2005). According to Harrison et al. (1985), the closure temperature of the biotite is 320 °C $\pm$ 30 °C.

5.1.1 (Mesozoic) phyllites/schists from the lower basement-cover complex

For sample CR4, two age spectra were obtained. Two slightly different plateau apparent ages of 124.1 ± 0.7 Ma (100% of ^{39}Ar released) and 119.2 ± 0.8 Ma (80% of ^{39}Ar released) were calculated for a single and three smaller grains, respectively (Fig.7a). The obtained dates overlap with the corresponding inverse isochron dates (123.5 ± 1.4 Ma and 118.9 ± 1.0 Ma, respectively). As discussed in the description of the sample, bigger mica grains are commonly found in the microlithons whereas smaller grains are typical for the cleavage domains. Although the small grains possibly crystallised after the larger ones (based on the rock's texture) we cannot quantify the difference in time but cannot significantly exceed 5 m.y. (equal to the difference in

the plateau ages). The difference in the plateau ages can alternatively attributed to a diffusion-controlled process that originates within the variation in the grain size. Thus, the date of ca. 125 Ma is interpreted as the cooling age of the rock.

For sample CR10, two sets of relatively small white micas were analysed. Both apparent age spectra show evidence for partial argon loss and the individual steps for both of them are roughly constrained between ca. 128 and 112 Ma. For the six-grain dataset (black line - Fig.7b), the third step produced the oldest date, 126.8 ± 0.9 Ma, which can be considered as the minimum age of an older component and it is very close to plateau apparent age obtained for sample CR4 (i.e. 124.1 ± 0.7 Ma) from the same unit. Six out of the 11 steps yield a weighted date of ca. 115 Ma (67% of ^{39}Ar released) which is similar to the small grains of CR4 (119.2 ± 0.8 Ma). Despite a large MSWD value linked to the high radiogenic content of the sample, these dates overlap with the inverse isochron date of 118.3 ± 3.4 Ma. For the eight-grain dataset (light grey line - Fig.7b) the central part of the spectra (62% of ^{39}Ar released) yielded a weighted mean date of ca. 125 Ma and a meaningless inverse isochron date of 119.0 ± 8.1 Ma. The shape of the two apparent age spectra suggests that several reservoirs contribute to the released argon; yet the convex pattern first described by Wijbrans and McDougall (1986) was not observed. This could indicate that, in addition to the two white mica end-members, argon was released from a third component such as an interlayered chlorite that partly replaced muscovite. Overall, the age of the sample can be constrained between ca. 112 and 128 Ma. This is supported by the total fusion age of 126.6 ± 0.5 Ma for a single-grain white mica (dark grey line - Fig.7b) that is very close to the assumed older end-member. In summary, the most representative age for this sample, ignoring all the complexity involving multi-grain analysis, should be around 125 Ma.

For sample SM15 three single white mica grains were analysed (Fig.7c). The smallest one yielded a convex age spectrum (black line) which is reminiscent of the spectra described by Wijbrans and McDougall (1986) for mixture of mica populations. However, the other two gave reasonably flat degassing patterns with 95.4 ± 0.8 Ma (plateau age; 64% of ^{39}Ar released; medium grey line) and 95.9 ± 0.4 Ma (total fusion age; dark grey line) (Fig.7c). The dates obtained overlap with the calculated inverse isochron dates. These dates are indistinguishable within error with those obtained from samples SM40 (ca. 98 Ma) and SM56 (92.2 ± 1.9 Ma) (see below) from the same Mesozoic schists from the eastern part of the study area.

For sample SM40, three relatively large white mica grains were individually dated. All of them produced flat to weakly concave age spectra with total fusion ages in the range 97 - 100 Ma, similar to the corresponding inverse isochron dates (Fig.7d). Note the large MSWD values and the error bars due to the clustering of the data points near the abscissa. The reproducibility of the results for the three grains suggests an age of 98 ± 2 Ma as the most representative cooling age for this sample.

Five smaller white mica grains separated from sample SM56 display a complex, partially saddle-shaped spectrum that is usually interpreted as due to excess argon contamination (Fig.7e inset). In the $^{36}\text{Ar}/^{40}\text{Ar}$ vs. $^{39}\text{Ar}/^{40}\text{Ar}$ plot, the data points form a linear array corresponding to an intercept date of 93.1 ± 4.0 Ma, with an initial $^{40}\text{Ar}/^{36}\text{Ar}$ value of 1843 ± 74 . Correcting the primary age spectrum with this initial argon ratio, a plateau age of 92.2 ± 1.9 Ma can be calculated for 70% of released ^{39}Ar (Fig.7e). This age is only ~4-8 m.y. younger than that of the SM40 probably as a result of a smaller grain size or different chemical properties.

5.1.2 Paragneisses and orthogneisses from the upper basement slice

5.1.2.1 Paragneiss of unknown protolith age embedded in basement orthogneisses

Both biotite and white mica were separated from sample SM42 (Fig.7f). The single grain biotite age spectrum shows typical argon pattern with young dates in the first heating increments at about 30 Ma that progressively increase to a relatively tight group of dates between ca. 140 and 150 Ma (mean date of 145.7 ± 2.1 Ma; 57% of ^{39}Ar released). However, no reasonable plateau age can be calculated. The calculated inverse isochron date is 141.4 ± 2.3 Ma. This is identical within error with the 146.9 ± 3.0 Ma total fusion age calculated by Lips et al. (2000) from white micas of a mylonite of the Vertiskos Unit further southeast. From the same sample, three single white mica grains of same size were analysed. One of them yield a saddle-shaped spectrum indicative for excess argon (light grey line - Fig.7f). However, no linear array was observed in the inverse isochron plot and no correction could be applied to the age spectrum. The other two spectra (dark grey and medium grey lines - Fig.7f) yield more concordant age patterns with total fusion dates of 138.6 ± 0.6 Ma and 126.5 ± 0.5 Ma, respectively (inverse isochron dates of 137.5 ± 1.1 and 127.8 ± 2.2 Ma). Complexity on calculating a single age for this particular sample comes from the fact that the three white micas have recorded different apparent ages. This can be the result of variable excess argon incorporation or due to complex chemical variations. However, based on the youngest reasonable date (possibly the least affected by excess argon) it seems that the sample cooled below the blocking temperature at maximum at ca. 126 Ma. This sample is more likely part of the intercalated Palaeozoic sequences within the basement and the older age spectra obtained are more probably the result of partial reset of the system

during an event around (at maximum) 126 Ma. This conclusion is supported by the fact that the circa 125 Ma event is already well constrained from the samples CR4 and CR10 (described above) and from the samples SM78 and SM9 that will be described below.

5.1.2.2 Triassic Arnea Magmatic Complex

One white mica and one biotite grain were dated from sample SM78 (Fig.7g). The white mica yield a well-defined plateau age of 123.1 ± 0.5 Ma (97% of ^{39}Ar released) (black line) and an identical inverse isochron date of 123.0 ± 0.7 Ma with atmospheric initial argon. This age is very similar to those obtained from CR4 and CR10 few kilometres to the south. From the same sample, the biotite produced a convex age spectrum with maximum dates scattering between 55 and 60 Ma (grey line) (Fig.7g). A plateau age was calculated at 59.7 ± 0.7 Ma (36% of ^{39}Ar released) but no reliable inverse isochron age could be calculated. The age difference between the two minerals from the same sample cannot be interpreted in terms of their closure temperature differences as this would involve a period of about 60 m.y.. Due to its higher sensitivity to thermal overprint, it is likely that the biotite shows evidence for, almost complete, reset during late processes. This scenario is indeed compatible with the intrusion in the area of voluminous plutons during the Early Eocene (e.g., de Wet et al., 1989; Frei, 1996).

Two white micas were dated from sample SM9 both producing identical plateau ages (124.3 ± 0.5 Ma for 86% ^{39}Ar released and 124.6 ± 0.5 Ma for 98% of ^{39}Ar released) which are also similar to the calculated inverse isochron dates (Fig.7h) and to that of the white mica of sample SM78 from the same unit.

5.2 LA-ICP-MS U-Th-Pb monazite and U-Pb zircon dating

Two samples from the eastern and northern parts of the study area were selected for LA-ICP-MS *in situ* U-Th-Pb monazite dating in-context in thin sections and U-Pb zircon dating on separated minerals: one sample (SM24) comes from the upper basement slice and one sample (SM15) from the lower basement-cover complex (Fig.3).

Monazite grains from both samples display similar compositional variation and belong to the monazite-Ce species. Their P_2O_5 content varies between 27.32 and 31.49 wt.% and the UO_2 content is for most of the grains low (<0.1 wt.%). The REE, Th, Y and Ca contents vary: for Ce_2O_3 from 27.81 to 34.81 wt.%, for La_2O_3 from 10.53 to 14.30 wt.%, for Pr_2O_3 from 1.75 to 4.74 wt.%, for Nd_2O_3 from 8.36 to 14.86 wt.%, for ThO_2 from 0.6 to 16.77 wt.%, for Y_2O_3 from zero to 4.98 wt.% and for CaO from 0.35 to 2.44 wt.%. The isotopic datasets are given in Appendix A.2 for monazite and Appendix A.3 for zircon.

5.2.1 Schist from the lower basement-cover complex

Sample SM15 contains homogenous monazite grains with no obvious zoning in major elements (Fig.8a). Huttonite substitution varies up to 9% whereas brabantite substitution ranges between 3 and 10%. No evidence for common Pb is found in Fig.9a. Monazite grains found in the matrix and as inclusions (in garnet, kyanite and white micas) were dated. The obtained concordant dates range from 310 to 128 Ma. This age scatter reflects differences between individual grains and/or heterogeneities within single grains. Monazites from this sample are commonly decomposed at their outer parts into a corona made of apatite(ap)-allanite(all)-epidote(ep) according to the reaction (Fig.8a):

Similar REE-mobilisation reactions have been described in amphibolite-facies metamorphic rocks elsewhere (e.g., Broska and Siman, 1998; Finger et al., 1998). Such textures depend on the composition of the metamorphic fluids (Ca bulk content and Ca/Na ratio) in addition to the P-T conditions (Majka and Budzyn 2006; Budzyn et al., 2011; Krenn et al., 2012; and references therein). We note here that only the monazites grains found in the matrix are surrounded by these coronas whereas the monazite grains protected from fluid interactions (as inclusions in garnet and kyanite) do not show any reaction textures. Quite commonly, different dates were obtained for the cores and rims of the decomposed grains. At the rims, the dominant date cluster is Early Cretaceous with a calculated concordia date at 132.5 ± 0.3 Ma (Fig.9a). Concordant core dates (or dates from non-decomposed monazites) are found between ~310 and 230 Ma with a dominant Late Permian cluster (concordia date of 257.4 ± 1.1 Ma; Fig.8a) (Figs.8a,9a). Brabandite or huttonite substitutions show no correlation with the calculated dates.

Concordant zircon U-Pb ages scatter from 2357 to 122.7 ± 2.1 Ma (^{206}Pb - ^{238}U ages); the youngest concordant date is 216.7 ± 3.2 (^{206}Pb - ^{238}U age) (Fig.9b). More than half of the zircon grains dated lie in the range 216 to ~300 Ma and the majority of them at 248.2 ± 1.3 Ma (concordia age; Fig.9b).

5.2.2 Paragneiss from the upper basement slice

Sample SM24 revealed patchy monazite zoning in back-scattered images (Fig.8b). For this sample, monazite grains found both in the matrix and as inclusion in garnet and micas were dated. Huttonite substitution varies up to 2.5% whereas brabantite substitution ranges between 3

and 11%. As seen in Fig.9c there is no evidence for the presence of common Pb in these monazite grains; the age scatter corresponds to differences between individual grains and/or to heterogeneities within single grains. The obtained concordant dates range from 362.2 ± 3.7 Ma down to 208.6 ± 2.3 (^{232}Th - ^{208}Pb ages). The majority of the concordant dates cluster around 300 - 280 Ma; a concordia date at 302 ± 0.8 Ma was calculated for some of these grains (Fig.9c). Brabandite substitution shows a positive correlation with the obtained dates.

Age scatter is also evidenced by the zircon analyses (Fig.9d). The majority of dates are concordant or slightly discordant. The obtained dates range from 670 to 570 Ma and from 400 to 300 Ma; the youngest concordant date is 307.2 ± 3.8 (Ma) (Fig.9d).

5.3 Interpretation of the results

A wild variety of dates are revealed by LA-ICP-MS analyses on monazites and zircons from a schist and a paragneiss (Fig.9). Based on stratigraphic criteria, no deposition age can be assigned to these two samples. However, a great number of various pre-220 Ma dates can be assigned to the crystallisation ages of what we interpret as detrital monazite and zircon grains. In particular, the most visible age clusters can be found approximately at 230-250, 300-360, 400-460 and 500-600 Ma. These ages can be directly related to Early Mesozoic - Palaeozoic magmatic -and metamorphic- events recorded everywhere in the region (e.g., Himmerkus et al., 2006; 2007; 2009a; 2009b; Turpaud and Reischmann, 2010). For sample SM15, the youngest almost concordant detrital zircon age is ~217 Ma and sets a maximum Late Triassic deposition age (Fig.9b). However, there is no known thermal event at that time and, thus, this single age cannot be used to infer the deposition age. Many concordant zircon ages are found at ~230-250

Ma (Fig.9b). Contributing sources are likely linked to the well-known event related to the intrusion of voluminous plutons collectively known, in the study area, as the Arnea-Kerkini Magmatic Complexes. Thus, based on the detrital monazite (Fig.9a) and zircon populations (Fig.9b) we consider that the deposition age of sample SM15 is post-230 Ma. For sample SM24, the youngest concordant zircon age is ~300 Ma (Fig.9d). This weakly constrains the maximum deposition age for this sample as post-Carboniferous. In addition, there are plenty (>20) of ~280-300 Ma concordant monazite ages as well as two concordant ages around ~210-220 Ma (Fig.9c). Hence, the maximum deposition age of this sample is, in all probability, ~210 Ma.

For sample SM15 (lower basement-cover complex) we identified a well-defined Early Cretaceous (~132 Ma) monazite age cluster that is related to re-crystallisation and isotopic resetting contemporaneous with REE-mobilisation and the formation of apatite-allanite-epidote coronas at the rims of matrix monazite grains (Figs.8a,9a). In the same sample, monazite cores and non-decomposed monazite grains (inclusions in garnet) preserve their initial isotopic compositions and the corresponding calculated ages range from Early Triassic to Carboniferous (Fig.9a). No correlation between brabantite substitution and the corresponding ages is found which ensures preservation of the Th-Pb ages and no disturbance of the isotopic system during the re-crystallisation process (Poitrasson et al., 1996; Seydoux-Guillaume et al., 2002; Eglinger et al., 2014). As a results, the obtained age clusters are considered geologically meaningful. Similar reaction textures around monazites are commonly described in amphibolite-facies rocks (e.g., Broska and Siman, 1998; Finger et al., 1998). Textural observations dictate that monazite coronas formed after garnet crystallisation as there are no coronas in monazites included in garnet grains. Although the P-T range of garnet formation is not defined for this particular sample, thermodynamic considerations for the whole unit implies that garnet crystallised

between 500 and 580 °C on a prograde path from the eclogite-facies to the amphibolite-facies whereas the maximum temperature reached in the thermal history is ~620 °C (Figs.9,A2 in Kydonakis et al., 2015c). Consequently, assuming similarities in terms of P-T conditions throughout the unit, monazites in our sample (SM15) re-crystallised, in all probability, either near the peak-temperature of the amphibolite-facies (~620 °C) or during the cooling path from the peak-temperature to the low-temperature boundary of the amphibolite-facies. In any case, regarding the uncertainties involved in our approach we consider the ~132 Ma age as a minimum age for monazite breakdown. On the contrary, the sample from the upper basement slice (SM24) lacks similar breakdown coronas or Cretaceous monazite ages which implies that this sample did not experience monazite re-crystallisation preserving the original detrital monazite isotopic compositions (Fig.8c).

Reliable ages were obtained by $^{40}\text{Ar}/^{39}\text{Ar}$ step heating dating on micas. A reference closure temperature of 420 ± 30 °C (Harrison et al., 2009) that roughly corresponds to greenschist-facies conditions was adopted for the white mica grains. The adopted closure temperature is lower than the maximum temperature reached during peak metamorphism and thus, the obtained argon ages can be interpreted as cooling ages (see Kydonakis et al., 2015c). Interpreting the age spectra is rather straightforward (Fig.7a-e,g,h) with the exception of the paragneiss embedded in basement orthogneisses (SM42) for which inheritance may cause meaningless dates (Fig.7f). However, even in this case consistent data were extracted from the most likely complete reset grain (medium grey line Fig.7f). Our results clearly document cooling below the closure temperature at 120-125 Ma for the western and northern parts and at 95-100 Ma for the central-eastern part of the study area. Although the age of the peak-pressure metamorphism is unknown, the age of ~132 Ma calculated for the amphibolite-facies overprint

to the east (Fig.9a) fits well with the 95-100 Ma cooling $^{40}\text{Ar}/^{39}\text{Ar}$ ages obtained from the same area (Fig.7c-e).

6 Discussion

6.1 The Chalkidiki block: geological structure and the inferred P-T-t path from peak metamorphism to mid-crustal and near surface arrival

A major syn-metamorphic thrust appears to bring a basement slice (clearly of Vertiskos Unit origin) on top of a basement-cover complex (i.e., Vertiskos Unit plus Circum-Rhodope belt) (Kydonakis et al., 2015b). Using the results of the latter authors, we have superposed our geochronology findings on their NW-trending cross-section (Fig.10). Recently discovered pelitic eclogites to the eastern part of the study area coincide with the deepest exposed part of the lower basement-cover complex (Kydonakis et al., 2015c). At this location, the metamorphic conditions are estimated at 1.9 GPa / 520 °C, for the peak event, and at 1.2 GPa / 620 °C for the amphibolite-facies overprint (Kydonakis et al., 2015c) (Fig.10). The timing of the eclogite-facies event is unknown. However, we argued here that the Early Cretaceous (~132 Ma; Fig.9a) breakdown and isotopic re-equilibration of detrital Carboniferous - Early Triassic monazites occurred during the amphibolite-facies conditions and in all probability either at, or shortly after the peak-temperature.

The metamorphic conditions experienced by the equivalent complex further to the west (exposed beneath an upper basement slice) decrease to blueschist/greenschist conditions; clearly

this part of the complex remained at shallower crustal levels than its eastern counterpart during metamorphism (Michard et al., 1994) (Fig.10). The age of the peak-pressure event there is unclear. However, based on the existence of Tithonian sediments that are involved in the thrust system and that contain neo-formed glaucophane, albite, sericite and epidote (Ricou, 1965), the high-pressure event can be tentatively defined as post-Late Jurassic in age.

Post-peak cooling of the Chalkidiki block is constrained by $^{40}\text{Ar}/^{39}\text{Ar}$ dating on micas. The deepest part of the exposed pile (eastern basement-cover complex) yielded the youngest ages that are between 95 and 100 Ma (Fig.10). Thus, this part reached mid-crustal levels by the early Late Cretaceous. However, the western counterpart of the complex reached the same crustal levels earlier and at around 120-125 Ma (Fig.10). Interestingly, this is exactly the time when the uppermost basement slice reached the same crustal level (Fig.10). This clearly demonstrates that thrusting in the study area must have ceased by the early Late Cretaceous because both sides of the thrust yield the exact same $^{40}\text{Ar}/^{39}\text{Ar}$ cooling ages (Fig.10). The inferred arrival at mid-crustal levels, as summarised above, fits with the discovery of Latest Cretaceous near-surface arrival as inferred from fission-track reverse thermal modelling (Kydonakis et al., 2014).

We also want to mention that the oldest cooling age recorded in the area is ~125 Ma. However, Lips et al. (2000) reported an older spot fusion $^{40}\text{Ar}/^{39}\text{Ar}$ plateau age at 143 ± 5 Ma from a basement mylonite close to our CR10 sample (Fig.3). Following the above discussion about inheritance and incomplete isotopic reset in the Palaeozoic basement, we suspect that the Jurassic age of Lips et al. (2000) is due to an incomplete reset and should not be interpreted as a cooling age. In fact, this Jurassic age is quite similar to those obtained in this study for incompletely reset biotite from sample (Fig.7f). Our argument for incomplete reset of the micas

from the basement is strengthened by the existence of an older, almost non-reset, age of 275.3 ± 7.5 Ma obtained a few kilometres to the south (Lips et al., 2000).

As a last note, we highlight the report of identical $^{40}\text{Ar}/^{39}\text{Ar}$ cooling ages (100-125 Ma) from the basement of the Pelagonia domain further to the west (see Figs.1,2) by Lips et al. (1998) and Schermer (1990) which hint for a possible common Cretaceous cooling history between the Pelagonia and Chalkidiki areas. This might also be supported by the documentation of Cretaceous anatectic melts dated at 117 ± 8 Ma by Schenker et al. (2015), a date which is close to the age of monazite breakdown (~ 132 Ma) in the Chalkidiki. However, the late stage low-temperature Cenozoic history between those two areas differ significantly with >50 Ma apatite fission-track (AFT) ages for the Chalkidiki (Kydonakis et al., 2014) and 25-45 Ma AFT ages for the Pelagonia (see Schenker et al., 2014 for age compilation).

6.2 Regional geochronology considerations on the Rhodope

6.2.1 Rhodope: from the (ultra)high-pressure event to surface arrival

In the Northern Rhodope Domain (NRD), detailed zircon and monazite dating studies carried out over the last decades have identified a number of distinct metamorphic/magmatic events which are, in turn, often tentatively correlated with large-scale geodynamic processes lacking, however, a general consensus for the evolution model.

The most common zircon metamorphic ages of the early high-pressure metamorphic event recorded in the NRD are Late Jurassic (circa 145 Ma) and were reported for garnet-kyanite

gneisses, amphibolitised eclogites and associated paragneisses (e.g., Liati, 2005; Cornelius, 2008; von Quadt et al., 2008; Krenn et al., 2010; Liati et al., 2011). Somewhat older zircon ages from mafic eclogites and related metapelites (Bauer et al., 2007), as well as 160 Ma zircons from migmatitic gneisses that intrude mafic eclogites in the ultrahigh-pressure (UHP) Rhodopean localities (Bonev et al., 2015), have both been used as arguments in favour of a pre-Upper Jurassic age of the (U)HP event. Few circa 75 Ma zircon metamorphic ages from an orthogneiss, a garnet-kyanite gneiss, a garnet-rich mafic rock and an eclogite (Liati et al., 2002; 2011; Bauer et al., 2007) were either attributed to a high-pressure event or related to an amphibolite-facies overprint. These Cretaceous ages are from an upper imbricate unit found in the NRD but due to the limited number of similar metamorphic zircon ages, it is unlikely that this event has a regional importance. Alternatively, these ages could correlate with the Upper Cretaceous magmatism (von Quadt and Peytcheva, 2005; Marchev et al., 2006; Peytcheva et al., 2007; von Quadt et al., 2010). A 126 Ma metamorphic age (Lu/Hf on garnet) was obtained from an upper imbricate unit (Kirchenbaur et al., 2012).

The oldest available EPMA monazite ages from the NRD are reported by Reischmann and Kostopoulos (2002), Hoinkes et al. (2008) and Nagel et al. (2011) who found apparent monazite ages at circa 180 Ma age and attributed monazite formation to the UHP event. In a recent work, Didier et al. (2014) reported, in a detailed study, few monazite cores with similar apparent LA-ICP-MS ages. The same authors, more importantly, reported a wealth of Mesozoic monazite ages that scatter between 115 and 165 Ma for the NRD. They calculated mean ages of 142 ± 11 Ma and 138 ± 10 Ma for the two studied localities and attributed the monazite formation to an upper amphibolite/granulite-facies event. Interestingly, our analysis supports the existence of a similar Early Cretaceous amphibolite-facies event recorded in the deepest part of

the Chalkidiki block (Figs.9a,10) thus linking the peak temperature events between these two Rhodopean domains that were only separated after the Tertiary extension through development of the Southern Rhodope Core Complex (Brun and Sokoutis 2004; 2007; see also Kydonakis et al., 2015b).

On the other hand, Mposkos and Wawrzenitz (1995) provided a 65 Ma age (Rb/Sr) which is indistinguishable from the 62 Ma age (U-Pb on zircon) reported by Liati et al. (2002) both obtained on late pegmatites that crosscut the regional foliation of the gneisses. Both these ages are similar to the 64.4 ± 1.4 Ma age reported by Bonev et al. (2015) for the rim of a zircon from an orthogneiss. Contrary to the timing of the (U)HP event in the Rhodope, it is commonly accepted that these ages set an absolute minimum for the end of the metamorphic episodes recorded by the Rhodopean gneisses. This is also in agreement with the existence of (i) Maastrichtian - Paleocene deposits that rest on basement gneisses (Boyanov et al., 1982; Goranov and Atanasov, 1992) which further implies that part of the eastern Rhodope was close to the surface by Latest Cretaceous and (ii) Eocene apatite fission-track ages (Kydonakis et al., 2014) which indicate that near surface conditions (temperature less than 120°C) were reached by Latest Cretaceous in the Chalkidiki block at the western end of the Rhodope.

This raises the next question that concerns the thermal history of the Rhodope between peak metamorphic conditions (Jurassic and part of the Cretaceous) and near surface arrival as deduced from the existence of Maastrichtian - Paleocene unconformable deposits and the upper Cretaceous crosscutting pegmatites.

6.2.2 Medium-temperature geochronology in the Rhodope: filling the Cretaceous gap

To address the previous question we will present data from the more robust medium-temperature geochronology system ($^{40}\text{Ar}/^{39}\text{Ar}$).

In the eastern NRD, the oldest available $^{40}\text{Ar}/^{39}\text{Ar}$ ages are circa 150 Ma from allochthonous orthogneisses (Bonev et al., 2010). However, these ages cannot account for the regional cooling as they pre-date peak conditions experienced by the Rhodopean gneisses (see section 6.2.1). Bonev et al. (2013) reported a 65 Ma $^{40}\text{Ar}/^{39}\text{Ar}$ age from an amphibolite located at the hanging-wall of the Byala Reka - Kechros dome in the eastern Rhodope but the excess argon in the low-temperature steps and the fact that no other similar ages are reported in the area suggest a rather local importance. Mukasa et al. (2003) reported a circa 45 Ma age (amphibole $^{40}\text{Ar}/^{39}\text{Ar}$) from a retrogressed eclogite located also at the hanging-wall of the Byala Reka - Kechros dome. More importantly, a great number of circa 40 Ma and younger $^{40}\text{Ar}/^{39}\text{Ar}$ ages were obtained from the imbricate units of the NRD and from the exhumed gneiss domes (e.g., Lips et al., 2000; Ovtcharova et al., 2003; Bonev et al., 2006; 2013; Márton et al., 2010). Consequently, this leaves a circa 100 m.y. time lag between the inferred (ultra)high-pressure conditions (roughly constrained at 140-160 Ma) and the event recorded by the $^{40}\text{Ar}/^{39}\text{Ar}$ system (around 45-60 Ma).

Based on regional considerations, the post-45 Ma $^{40}\text{Ar}/^{39}\text{Ar}$ ages are related to the early Aegean extension and the resultant exhumation of the Rhodopean core complexes rather than cooling of the Rhodopean gneisses after the peak metamorphic episode (see also Burg, 2012; Moulas et al., 2013; Brun et al., 2016). Indeed, severe re-working of the earlier deformation fabrics, exhumation of gneiss domes beneath low-angle detachments (Bonev et al., 2006; Brun and Sokoutis, 2007), extended magmatic activity that includes Latest Cretaceous-Oligocene plutons and Eocene-Oligocene volcanics and hydrothermal deposits (Pal'shin et al., 1975;

Marchev and Singer, 2002; Marchev et al., 2006; Marchev et al., 2010; Márton et al., 2010; Filipov and Marchev, 2011; Marchev and Filipov, 2012; Kaiser-Rohrmeier et al., 2013), all contributed to an increased thermal gradient in an active region affected by ductile extension and apparently precluded preservation of any pre-45 Ma medium-temperature isotopic record in the Rhodope. The inferred high thermal gradient is further reflected into the relatively young low-temperature thermochronology data from the NRD (see review in Kydonakis et al., 2014) and is in line with the existence of numerous Eocene-Oligocene zircon ages from kyanite eclogites, metapelites, metagabbros, biotite gneisses and pegmatites (e.g., Liati and Gebauer 1999; Liati, 2005; Cornelius, 2008; Bosse et al., 2009; Liati et al., 2011; Moulas et al., 2013). The latter zircon ages, instead of representing yet another high-pressure event in the Rhodope should be more likely related, from a geodynamic point of view, to core complex extension coeval with magmatic intrusions of the same age.

Consequently, the post-peak thermal evolution of the NRD can be addressed using the record of the Chalkidiki gneisses. Based on our new findings and on the detailed medium-temperature geochronology record obtained in the Chalkidiki block, we can safely propose that the Rhodopean gneisses arrived at mid-crustal levels by the early Late Cretaceous shortly after the regional amphibolite-facies overprint that occurred during the Early Cretaceous. Although the evidence for the early Late Cretaceous arrival at mid-crustal levels is completely erased in the NRD due to the effects of the Tertiary extension, it is clearly preserved in the Chalkidiki block that largely escaped the Tertiary thermal perturbation.

7. Conclusions

Prior to their separation by the exhumation of the Southern Rhodope Core complex in Eocene, the Chalkidiki block and the Northern Rhodope Domain underwent the same tectono-thermal history. We studied rock samples exposed at various structural positions within the Chalkidiki metamorphic pile in order to define the Mesozoic post-peak metamorphic evolution of the North Aegean. Based on the available literature data from the Northern Rhodope Domain and our data from the Chalkidiki block, a schematic P-T-t diagram is compiled in Fig.11. Our contribution to the evolution of the North Aegean can be summarised in two main points:

(1) The regional amphibolite-facies re-equilibration occurred in all probability at (or slightly before) 132 Ma based on U-Th-Pb LA-ICP-MS dating of monazites from a garnet-kyanite micaschist exposed at the deepest (eastern) part of the Chalkidiki block (Fig.10). The conclusion is based on isotopic reset of primary Carboniferous - Early Triassic monazite grains coeval with partial monazite destruction, REE-mobilisation and formation of a corona made of apatite, allanite and epidote. The suggested timing for the amphibolite-facies overprint (this study) is contemporaneous within error with the age proposed recently for the central/north Rhodope based on monazite dating (circa 140 Ma; Didier et al., 2014) thus, linking the Cretaceous history of the Chalkidiki block with the imbricates of the Northern Rhodope Domain further to the northeast.

(2) Based on the results of $^{40}\text{Ar}/^{39}\text{Ar}$ step-heating on micas, cooling and arrival at mid-crustal levels occurred at 95-100 Ma for the eastern and structurally lower parts of the Chalkidiki block whereas, the western, and structurally uppermost part of the system went through the same event at 120-125 Ma. (Fig.10). We propose that syn-metamorphic thrusting must have ceased in the Chalkidiki block by early Late Cretaceous as inferred from the existence of virtually identical $^{40}\text{Ar}/^{39}\text{Ar}$ cooling ages on both the hanging-wall and foot-wall of a major thrust that separates an

upper basement slice from a lower basement-cover complex (Fig.10). The obtained 120-125 Ma ages are similar to the $^{40}\text{Ar}/^{39}\text{Ar}$ cooling ages documented from the basement of the Pelagonia domain further to the west (e.g., Schermer, 1990; Lips et al., 1998). Juxtaposition of the “120-125 Ma” to the “95-100 Ma” subdomains of the Chalkidiki block occurred during the Tertiary extensional phase (Fig.10).

Having largely escaped thermal perturbations related to the Tertiary extension, the Chalkidiki block maintained a rather complete isotopic record from the amphibolite-facies overprint (at or slightly before 132 Ma; this study), through the greenschist-facies (95-125 Ma; this study) to near surface arrival (65 Ma; Kydonakis et al., 2014). These new findings adequately fill the Cretaceous lack of medium-temperature geochronology data in the area.

ACKNOWLEDGMENTS

This work was funded by the European Union FP7 Marie Curie ITN “TOPOMOD” contract 264517. KK is grateful to Dimitrios Kostopoulos for introduction to the geology of the Rhodope and for stimulating discussions and numerous fieldtrips over the last years. Frédéric Lecoœur (Géosciences Montpellier) is thanked for valuable help during the argon/argon analyses and Xavier Le Coz (Géosciences Rennes) for the thin sections preparation. The comments received by Nikolay Bonev and Filippo Schenker materially helped to improve the original manuscript and are greatly appreciated. Philippe Agard is greatly acknowledged for editorial handling.

Table 1. List of samples used for $^{40}\text{Ar}/^{39}\text{Ar}$ and U-Th-Pb geochronology. Mineral abbreviation scheme after Siivola and Schmid (2007).

Sample	Latitude	Longitude	Rocktype	Mineral assemblage (major/accessory)
<i>Lower basement-cover complex</i>				
<i>Western part</i>				
CR4	40.53	23.22	phyllite	qtz,phg,pg,chl,grt / zrn
CR10	40.45	23.52	phyllite	qtz,phg,chl / cal,rt,bt
<i>Eastern part</i>				
SM15	40.73	23.61	schist	qtz,grt,ky,phg,rt / st,chl,bt,ilm,ep,zrn,mon,ap,aln
SM40	40.76	23.41	schist	phg,qtz,par,grt,bt,st,chl,ky / mon,zrn,ilm,aln
SM56	40.44	23.65	schist	phg,qtz,par,grt,bt,chl / zrn
<i>Upper basement slice</i>				
<i>Paragneisses of unknown protolith age</i>				
SM24	41.13	23.21	schist	qtz,phg,grt,ky,bt / chl,mon,zrn,ap,rt,ilm
SM42	41.13	23.02	schist	qtz,phg,grt,bt,ilm,fsp / zrn,rt,chl,mon
<i>Triassic orthogneisses</i>				
SM9	40.91	23.21	orthogneiss	qtz,phg,fsp,bt / rt,zrn,ap
SM78	40.90	23.21	orthogneiss	qtz,phg,fsp,bt / rt,zrn,ap

Highlights

We present new geochronology data from the southwestern part of the Rhodope

The study area (Chalkidiki block) retains a rather rich Cretaceous isotopic record

Monazite breakdown at ~132Ma provides a minimum age for the amphibolite-facies event

Amphibolite-facies overprint predates the end of thrusting in the area

Cooling and arrival at shallow crustal levels occurred by the end of Early Cretaceous
