ABSTRACT

This study proposed a new reconstruction of the tectono-sedimentary evolution of the Lake Albert Rift based on a biostratigraphical, sedimentological and structural re-evaluation of the outcropping data and on an exceptional subsurface dataset.

The infilling of the rift consists of lacustrine deposits wherein two major unconformities dated at 6.2 Ma and 2.7 Ma were characterized, coeval with major subsidence and climatic changes.

Combined with the fault analysis, the evolution and distribution of the subsidence highlights a four-steps evolution of the rift after its initiation dated at 17.0 Ma.

The first phase (17.0 – 6.2 Ma) consists of low and diffuse extension associated with low accommodation rates ranging from 150 to 200 m/Ma. Restricted in the southern part of the basin, the depocenter location is poorly controlled by faults, meaning that the basin extension was potentially larger at this time.

The second time interval (6.2 – 2.7 Ma) shows an increase of accommodation rates with values reaching more than 800 m/Ma. These high rates combined with the location of the major depocenters down the bounding faults argue for a first true rifting phase.

Between 2.7 Ma and 0.4 Ma, the accommodation rates decreases to reach less than 400 m/Ma and the individualization of major depocenters continue down the major fault in the southern, and northwestern parts of the basin.

Finally, between 0.4 Ma and present-day, a late uplift led the formation of the Ugandan scarp.

Comparison of the Lake Albert Rift evolution with the data available in the rifts of both branches of the East African Rift System shows that most of the sedimentary basins experienced the same geometrical evolution from large basins with limited fault control during Late Miocene to narrow true rift in Late Pleistocene.

1. INTRODUCTION

Extending from the Afar triple junction in the north (northern Ethiopia) to the Funhalouro Rift (Limpopo Plain, Mozambique, Fig. 1a) in the south, the East African Rift System (hereafter referred to the EARS) is an incipient divergent boundary between three major tectonic plates: the Arabian, Nubian (African) and Somalian plates (Calais et al., 2006; Saria et al., 2014; Stamps et al., 2014, 2008). The rifts and associated sedimentary basins of the EARS are located on two broad elevated "domes", the Ethiopian and East African domes (Ebinger, 1989). These wide regions of anomalously high topography are related to the thermal and dynamic activity of one or several mantle plumes connected to the so-called African asthenospheric superswell or superplume (Burke, 1996; Ebinger and Sleep, 1998; George et al., 1998; Nyblade and Robinson, 1994; Pik et al., 2006; Ritsema et al., 1998; Simmons et al., 2007), potentially at the origin of the extension.

Although the EARS is one of the most extensively studied rifts in the world, several questions remain about (1) the age of the initiation of the rifts (e.g. Macgregor, 2015), (2) the age of the doming (pre- to post-rift; e.g. Pik et al., 2003), (3) the existence and the age of the rift shoulders (syn- or post-rift; e.g. Bauer et al., 2016, 2012, 2010a; Spiegel et al., 2007; van der Beek et al., 1998) and (4) the different stages of evolution of the rifts and their relationships with the deformation. In the present study, we mainly focus on this last point through stratigraphical and structural analysis of one of the EARS basins, the Lake Albert Basin (Uganda) located at the northern termination of the western branch.

Three main types of sub-basins can be defined along the EARS: (1) rifts valleys superimposed or filled by volcanic rocks and few sediments with uplifted margins (eastern branch of the EARS – e.g. Gregory rift), (2) rift basins with few or no volcanic rocks and little uplift of the rift shoulders (e.g. Tanganyika and Malawi rifts) and (3) non-volcanic rift basins with an uplifted margin on one or both sides (e.g. Turkana, Albert and Rukwa rifts). The age of the volcanic rift initiation is documented on the basis of volcanic infilling dating (e.g. Ebinger, 1989a; Ebinger and Sleep, 1998; George et al., 1998; Kampunzu et al., 1998; Nyblade and Brazier, 2002; Pouclet et al., 2016; Zanettin et al., 1983). Conversely, the age of initiation and evolution of the non-volcanic and non-uplifted rifts are poorly

known due to the absence of deep drillings reaching the substratum and the limited attention paid to the biostratigraphy of the sedimentary basins (e.g. Pickford et al., 1993; Van Damme and Pickford, 2003).

The aim of this study is to discuss the geological evolution of the Lake Albert Basin on the basis of new data (wells and 2D seismic dataset) and analysis of the outcropping sediments (biostratigraphy and sedimentology). Our objective is to propose (1) an age model for the sedimentary infilling and its sequence stratigraphic framework and (2) a new tectono-stratigraphic calendar for the Lake Albert Basin evolution.

2. REGIONAL SETTINGS

2.1. THE EAST AFRICAN DOME RIFT SEGMENTS

The EARS is divided into two branches, an eastern and western branch, surrounding an Archean craton and lying on Proterozoic mobile belts and following their preexisting crustal-scale fabric trends (e.g. Chorowicz and Sorlien, 1992; Corti et al., 2007; Morley, 2010). The eastern branch (or Kenyan rifts) extends from Lake Turkana in the north to a diffuse zone of extension referred to the Tanzanian Divergence in the south (Fig. 1a). This eastern branch is characterized by moderate seismic activity and significant magmatism. In contrast, the western branch, extending from the Azwa Precambrian lineament in the north (Fig. 1a-b) to Lake Malawi in the south, corresponds to a succession of seismically active asymmetric rifts segmented by transverse fault zones (TFZ; e.g. Bosworth, 1985; Chorowicz and Sorlien, 1992; Ebinger, 1989b; Morley, 2010, 1999; Rosendahl, 1987; Fig. 1b) and displays an alternating sense of asymmetry (Ebinger, 1989a). One of the characteristics of this western branch is the rare volcanic activity restricted to several provinces such as Toro-Ankole (≈ 0.6 Ma), Virunga (first episode at 12.6 Ma), South Kivu (≈ 21 Ma) and Rungwe (≈ 8.6 Ma) (see review in Kampunzu et al., 1998 and Pouclet et al., 2016). South of the East African dome, the EARS expose a diffuse pattern of extension connected to the Davie Ridge in the south-east and propagating toward Namibia in the south-west where the Okavango Delta (Botswana) shows an incipient rifting stage (Fig. 1a).

Along the eastern branch, magmatism began in the Late Oligocene – Early Miocene (Baker et al., 1971; Bishop et al., 1969; McDougall and Brown, 2009; Morley et al., 1999c) and ages tend to document an overall southward migration of the rifting through time until the Tanzanian Divergence (e.g. Baker, 1987; Baker et al., 1971; Ebinger, 1989a; Foster et al., 1997; George et al., 1998; Kampunzu et al., 1998, 1991). The timing of the western branch is uncertain because of the rare volcanic activity. On the basis of the oldest volcanic episodes occurring in the Virunga between 12.6 (Bellon and Pouclet, 1980) and 11 Ma (Kampunzu et al., 1998 and literature therein), the western branch is usually interpreted as being younger than the eastern branch. Nevertheless, recent studies based on new sediment analysis and dating (biostratigraphy, magnetostratigraphy) indicate that the rifting initiation probably began as soon as the late Oligocene in the Rukwa rift (Roberts et al., 2012, 2010).

For a long time, the direction of the present-day extension related to the EARS opening was debated as being either an oblique opening model consisting of a SE drifting of the Somalian plate (e.g. Chorowicz, 2005, 1990; Chorowicz and Mukonki, 1980; Daly et al., 1989; Kazmin, 1980; Scott and Rosendahl, 1989; Tiercelin et al., 1988; Wheeler and Karson, 1994) or an orthogonal opening model based on the actual overall E-W extension with a direction of extension that slightly varies along the two branches (e.g. Delvaux, 2001; Delvaux and Barth, 2010; Ebinger, 1989a; Lezzar et al., 2002; Morley, 2010, 1999; Morley et al., 1999b). Recently, both earthquake slip vector data and GPS geodesy studies support the second hypothesis of a general E-W extension (e.g. Calais et al., 2006; Delvaux and Barth, 2010; Saria et al., 2014, 2013, Stamps et al., 2014, 2008).

2.2. THE ALBERTINE RIFT SYSTEM

The Lake Albert Basin belongs to the Albertine Rift System which includes Lake Albert, Lake Edward and Lake George (Pickford et al., 1993). Bounded by the Azwa lineament to the north and by the Virunga volcanic province to the south (Figs. 1a & 2), this system is characterized by an outstanding 5000 meter high relief located between Lake Albert and Lake Edward, the Rwenzori Mountains (Fig. 2).

The Lake Albert Basin was traditionally considered as an asymmetric half-graben dipping to the north-west where the major bounding Bunia fault system (Fig. 2) probably led to the uplift of the 2100 m high Blue Mountains (Ebinger, 1989a and gravity modelling of Ebinger et al., 1991; Karner et al., 2000; Upcott et al., 1996). The eastern boundary consists of westward-dipping antithetic Toro-Bunyoro and Tonya fault systems (Fig. 2) which controlled the uplift of the 1200m high topographic escarpment observed at the eastern border of the lake (difference in elevation with the lake level of $\approx$ 400m). By matching the observed and modeled topography with free-air gravity, Karner et al. (2000) assumed a crustal extension ranging from 6 to 16 km for a sediment thickness up to 5 km deposited during 5 Ma. Recently, on the basis of new seismic data and gravity re-processing, Karp et al. (2012) shows that the Lake Albert Basin is rather a "full-graben" that *"has subsided symmetrically and continuously in the Late Cenozoic along two extensive boundary fault systems on either side of the basin"*.

Focal mechanism (Delvaux and Barth, 2010) and GPS geodesic studies (Calais et al. 2006; Stamps et al. 2008) indicate that the Lake Albert Basin is currently opening at 2 mm/a in a predominantly WNW-ESE extensional stress regime. However, localized earthquakes showing strike-slip solutions (e.g. Koehn et al., 2010; Ring, 2008), rare positive flower structures (splay geometry of faults) and anticline structures (Abeinomugisha and Kasande, 2012) suggest that the Lake Albert Basin might have experienced potential strike-slip movement during its evolution. These discussions about an oblique component could be explained by the basement structure heritage. South of the Nile, the Lake Albert Basin is located at the interface of the Archean Congo Craton and the Paleo- to Meso-Proterozoic Kibaran mobile belt of which the basin follows its roughly NE–SW trend.

The age of the rifting initiation in the Lake Albert Basin is debated because the first Early Miocene sediments preserved in the basin have not been considered as syn-rift deposits but rather as *"pre-rifting fluvial sediments"* (Ebinger, 1989a; Hopwood and Lepersonne, 1953). Based on the biostratigraphy available at this time, the first syn-rift lacustrine sediments were considered to be Late Miocene in age (8 Ma; Ebinger, 1989a; Pickford et al., 1993), following a first volcanic episode of the Virunga Province dated from 12.6 to 9.0 Ma (Kampunzu et al., 1998; Pouclet et al., 2016 and literature

therein). This first major rifting phase might have been responsible for the formation of a paleo-lake (Lake Obweruka) covering the entire Albertine Rift area until the Rwenzori uplifted around 2.5 Ma (Pickford et al., 1993; Taylor and Howard, 1999; Van Damme and Pickford, 2003). Recent petroleum exploration and biostratigraphical investigations argue for an older rifting initiation, uppermost Early Miocene in age (≈ 17.0 Ma; Abeinomugisha and Kasande, 2012).

The origin of the Rwenzori Mountains is still debatable. Both thermochronological (Bauer et al., 2016, 2015, 2012, 2010a; MacPhee, 2006) and biostratigraphical data (e.g. Pickford et al., 1993) indicated a last uplift during the Upper Pliocene to Pleistocene, mainly around 2.5 Ma. A first stage of exhumation probably compensated by erosion occurred during Jurassic times (Bauer et al., 2012). Seismological data, (Homuth et al., 2016; Wölbern et al., 2010) shows the absence of a crustal root and thinned crust below the Rwenzori Mountains. On the basis of microtectonic measurements and focal mechanism analysis, the tectonic setting of the Rwenzori Mountains is assumed to be dominated by strike-slip movements (e.g. Koehn et al., 2010; McConnell, 1959; Ring, 2008; Sachau et al., 2016). Two main mechanisms are proposed to explain the extreme uplift of the Rwenzori Mountains: (1) isostatic response related to the removal of crustal material in the hanging wall of a normal fault (Koehn et al., 2016, 2010); the horst uplift is thus the consequence of the "cantilever effect" (Kusznir and Ziegler, 1992), and (2) the delamination of the lower crust and mantle lithosphere due to pre-existing weak-zones (Wallner and Schmeling, 2016, 2010).

By performing a sedimentary study of the Kisegi-Nyabusosi area outcrops, Roller et al. (2010) defined a four-staged evolution of the Lake Albert Basin: (1) from 14.5 to 10 Ma, the first stage corresponds to a sag basin with little accommodation space creation infilled by fluvial sediments. (2) From 10.0 to 4.5 Ma, the second phase is characterized by the creation of limited accommodation space and records successive rises in the lake level, as indicated by a transition from a distal fluvial plain to a lacustrine environment. The increase in the accommodation/sediment supply ratio is believed to record an initial rifting activity. (3) Between 4.5 and 2 Ma, the third stage corresponds to a classic rift controlled by sediment-supply rather than by accommodation. The lacustrine deposits record lake-level highstands. (4) Finally, from 2 to 1.5 Ma, an overall increase in the subsidence

associated with a significant sediment supply is responsible for the acceleration of the uplift of the flanks. This infilling corresponds to stacked transgressive cycles from a fluvial to lacustrine environment.

3. MATERIAL AND METHODS

3.1. DATA AVAILABLE

The study of the Lake Albert Basin presented herein is based on the analysis of field and subsurface data. The field data consist of numerous short sections (from 5 to 170m, Fig. 3) on which both sedimentological and biostratigraphical analyses were performed, most of them having previously been studied by Pickford and co-authors (e.g. 1993). The outcropping areas are restricted in (1) the Kisegi-Nyabusosi area, at the northern tip of the Rwenzori Mountain (the so-called Semliki area), (2) in the Kaiso-Tonya flat, on the central eastern shore of Lake Albert and (3) in the northern part of the lake (Fig. 3). The subsurface dataset consists of approximately 300 2D seismic lines and 20 interpreted wells. Here, we present the interpretation of 11 regional seismic lines and five wells selected in order to represent the characteristic geometrical configurations of the Lake Albert Basin (sections 1 to 11 and wells 1 to 5; Fig. 3). In addition to five exploration wells, two fictive wells resulting from seismic interpretation (well A and B; Fig. 3) are presented in order to illustrate the most subsiding part of the basin. Unfortunately, these data are limited to the Ugandan side of Lake Albert.

3.2. BASIN-SCALE CORRELATIONS

Stratigraphic cycles – transgressive and regressive cycles – were interpreted from the evolution of the sedimentary environments (alluvial to distal lacustrine). These environments were defined on the basis of (1) sedimentary facies analysis of the outcrops, (2) the palynomorph content (pollens and spores in wells and outcrops) and (3) the well-log signatures of the sedimentary facies.

By definition, the stratigraphic cycles are bounded by Maximum Regressive Surfaces (MRS – Catuneanu et al., 2009) which correspond to the most proximal environment. In between, Maximum Flooding Surfaces (MFS; Posamentier and Allen, 1999) are defined. These surfaces are marker of the most distal environment and represent turnaround surfaces between transgressive and regressive

trends. Unconformities (Un; Embry, 2009) can occur during the regression and record either an aerial erosional surface or a downward shift of the sedimentary facies in a subaqueous environment.

Depending on the distance separating the wells, basin-scale correlations were performed in two different ways. In the case of wells separated by several kilometers (e.g. Kaiso-Tonya flat), correlations are made by applying stacking pattern techniques (Homewood et al., 1992; Van Wagoner et al., 1990, 1988) and then validated by the characteristics of the algae, pollen and spore trends (e.g. maximum amount of *Botryococcus*, *Pediastrum*, *Podocarpus* or *Poaceae*). Three cycle orders were defined, possibly 3rd, 4th and 5th; the latter was only used for the stacking pattern correlations. When wells are separated by several tens of kilometers, correlations were made in favor of the major stratigraphic cycles and were strongly constrained by the palynomorph records.

3.3. SEISMIC INTERPRETATION

The 2D seismic reflection dataset mainly displays a parallel configuration of reflection, with very few localized divergent or sigmoidal (prograding clinoforms) reflectors. Consequently, the classical seismic stratigraphy analysis using truncations (Vail et al., 1977) and offlap migration ("shoreline trajectory" *sensu* Helland-Hansen and Martinsen, 1996) cannot be applied successfully in the Lake Albert Basin. The only variations concerned the seismic facies packages and the continuity, amplitude and frequency of the reflectors. This implies that the stratigraphic surfaces (MFS, MRS, Un) were first defined from the wells and then propagated to the seismic lines. The structural analysis (mainly fault distribution and geometries) was performed using several reasonable vertical exaggerations (1:1 to 1:2).

Both sediment thickness and sedimentation rate maps were compiled for three time intervals. Sedimentation rate maps (under-compacted) are used as a proxy of the spatial distribution of the accommodation rate. In addition, eleven regional sections based on the 2D seismic interpretation illustrate the relationships between the structure and sedimentation. Regional 2D sections and thickness maps (isopach maps) were converted into depth using a time (ms) to depth (m) conversion law constrained by the wells and provided by the petroleum company Total.

3.4. AGE MODEL

Pickford et al. (1993) divided the outcropping Neogene and Quaternary sedimentary succession of the Lake Albert Basin into eight lithostratigraphic formations in the Kisegi-Nyabusosi area and into four major formations in the Kaiso-Tonya area (see Fig. 3 for the location and §1.4.2 for a detailed description). This subdivision of the sedimentary infilling is based on lithologies and biostratigraphic content such as mammals (e.g. Pickford et al., 1993 and literature therein), mollusks (Van Damme and Pickford, 1994) and, more recently, pollens, pores and algae (Lukaye, 2009; Shaw et al., 2009). Mammals are the only fossils that can be used for calibration on the international chronostratigraphic chart (Gradstein et al., 2012). Mollusk associations are limited to the Albertine rift area and Neogene pollens and spores mainly record environmental changes driven by the climate. In this study, vertebrate biozonations are calibrated in ages in (1) Kenya, where radiometric dating of tuffs and lavas constrain the age of the vertebrate taxon ranges or, when species were not described in Kenya, (2) in favor of the international European vertebrate biozones chart. The time range of each vertebrate taxon is reported on the stratigraphic sections (and thus, on the associated lithostratigraphic formations) and, according to their degree of evolution, classified into five main categories: primitive, early, mature, late and end of phylum. For each formation, the common range of the different characteristic vertebrate species defines a time-interval for the considered lithostratigraphic units (Yalden, 2011).

The first limit of this approach is the use of mammals as dating elements because (1) their preservation is highly controlled by the type of sedimentary environment, (2) for some time intervals, few (or no) species were sampled and (3) the time range of some species is poorly constrained. The second limit is that these mammals were only found on outcrops. Thus their ages need to be propagated in the subsurface data using sequence stratigraphy and paleo-environmental data (pollens and spores record) correlations.

For these reasons, we proposed to test the outcrop age model extended to the wells by doing a comparison with the regional paleo-climatic charts. The basin-scale climatic chart is based on the following assumptions: humid conditions are related to periods of maximum lake growth emphasized by *Botryococcus* algae and more arid conditions correspond to a minimum lake extension (large

alluvial plains and littoral environments) highlighted by an increase in aerial flora, i.e. *Poaceae*. Transitions from humid to arid conditions correspond to a sharp decrease in water depth, i.e. unconformities. This basin-scale climatic signal is then compared to the dated regional climatic chart, here mainly the one of Bonnefille, (2010) based on the "tree cover" of East-Africa estimated from the percentages of tree and shrub pollens.

3.5. ACCOMMODATION SPACE MEASUREMENT

In order to quantify the vertical displacement within the Lake Albert Basin (subsidence and uplift), the accommodation space was measured using the backstripping method (e.g. Watts and Steckler, 1979). Accommodation is defined as the space created in the sea, or in a lake, in response to the vertical movement of the base of the basin (relative to lithospheric/mantellic deformation) and the lake level, a consequence of the hydrological budget related to climatic variations. This is not a direct measurement of the subsidence because we were not able to remove the lake level variations related to the climatic variations. Nevertheless, a change in the vertical facies from a shallow lake to a coastal plain or alluvial plain environment, suggests moderate variations in the lake level and thus indicates that most of the accommodation space creation is controlled by tectonic vertical movements.

Accommodation measurements require: (1) previously defined (§ 3.2) time-lines (turnaround surfaces, MFS and MRS or unconformities, Un) and are referred in absolute ages (§ 3.3.4), (2) porosity data deduced from well-log signatures and cuttings and (3) an estimation of the paleo-depths interpreted from facies analysis (outcrops analysis, well-log signatures and palynological content). The decompaction is based on the depth-porosity coefficient for the different lithologies, here mainly clay and sand. Different scenarios were tested by applying uncertainty ranges associated with the absolute ages, paleo-depths and lithologies.

Accommodation space variations were measured in five wells (wells 1 to 5; Fig. 3). In addition, two "fictive wells" interpreted from the 2D seismic lines aim to illustrate the accommodation variations in the most subsiding parts of the basin where no wells are available (wells A and B; Fig. 3).

4. RESULTS

4.1. DEPOSITIONAL MODEL AND SEQUENCE STRATIGRAPHY ANALYSIS

4.1.1. Depositional model

Five major facies associations (referred as Fa) were defined on the outcrops and well-logs in the infilling of the Lake Albert Basin (Fig. 4): distal "deep" lacustrine (Fa1), proximal "shallow" lacustrine (Fa2), deltaic lacustrine (Fa3), lacustrine shoreline and embayment to lacustrine coastal plain (Fa4) and alluvial plain environments (Fa5).

4.1.1.1. Distal "deep" lacustrine (Fa1)

It essentially corresponds to homolithic, massive or horizontally laminated dark grey clays. Some intervals can be either more silty or organic-rich with abundant *Botryococcus* algae. The biological content is poor, with rare *in-situ* freshwater bivalves (with connected shells) but no bioturbations.

The depositional setting is the one of a perennial lake (freshwater algae and bivalves) as indicated by the lack of mud-cracks or soils (even hydromorphic).

In the subsurface, the well-log signature of this environment consists of a high natural radioactivity (gamma-ray) and a symmetrical evolution of the density and porosity (Fig. 4). More radioactive intervals correspond to an organic-rich clayey interval.

4.1.1.2. Proximal "shallow" lacustrine (Fa2)

These environments consist of an alternation of clays (Fa1) and coarse- to fine-grained sands several to tens of centimeters thick. These sandy beds are most of the time poorly sorted, structure-less (massive) and do not show either normal or reverse grading. Some of them show crude planar horizontal laminations (upper flow regime) or provide evidence of fine-grained sand with bedload current ripple cross-beddings (no occurrence of climbing current ripple cross-beddings). *Pediastrum* are observed in the clayey intervals.

These lacustrine beds do not correspond to either classical lacustrine turbidites (no normal grading, no Bouma or Stow sequences; e.g. Wells et al., 1999) or to hyperpicnal flows (no reverse grading, no climbing current ripples; e.g. Olariu and Steel, 2009; Olariu et al., 2010). They look similar to sheet-

flood deposits directly supplied from the aerial domain (structure-less, poorly graded and sorted) such as the classical examples of Turner (1973) or Mutti et al. (2000).

The well-log is characterized by high variations (thin peaks) of radioactivity (low and high gamma-ray) and porosity values (from clay to sand; Fig. 4). The overall gamma-ray trend generally exposes a slight funnel shape (slight coarsening upward trend).

4.1.1.3. Lacustrine delta (Fa3)

Lacustrine deltas are mainly made up of homolithic coarse-grained sand organized in coarsening upward units (from medium- to coarse-grained sand) of several meters with 2D-3D (sinuous crest) to 3D current megaripples, some of which are climbing (mixed bedload – suspended-load transport; Allen, 1981). On another scale, these megaripples are superimposed onto sand bars (wavelength > 10m) forming compound cross-beddings. Both the bars and megaripples migrate in the same direction. The clayey intervals contain a significant amount of *Pediastrum* algae.

The occurrence of climbing megaripples and compound cross-beddings (indicating sand bars) are characteristic of mouth bars along a river delta-front system (e.g. Coleman and Wright, 1975; Galloway, 2001; Olariu et al., 2012).

The high porosity and funnel shape (coarsening upward) of the low gamma-ray values are a characteristic response of a prograding mouth bar in the well-logs.

4.1.1.4. Lacustrine shoreline and embayment (Fa4)

These deposits correspond to green to grey clays interbedded by fine- to medium-grained sandy beds (from tens of centimeters to two meters thick). The clays are green to grey, massive and occasionally silty and frequently lignite-rich. The sandy facies mainly consist of well-sorted highly bioturbated and clean sandstones with current and avalanching ripples and megaripple cross-beddings and locally numerous gastropod debris (coquina) and various plant residues.

These facies suggest a deposition in a lacustrine shoreline to coastal plain environment with embayment and marshes (lignite).

The clayey facies of this environment are characterized by high radioactivity (gamma-ray), high porosity and low density values; the last two curves evolve symmetrically and record woodland plant and lignite debris (Fig. 4).

4.1.1.5. Lacustrine coastal plain (Fa5) and river channels (Fa6)

Lacustrine coastal plain (Fa5) environment consists of massive dark-grey to green clays with plants debris, hydromorphic soils and a significant amount of aerial *Poaceae* (*Gramineae*) pollens.

River channel (Fa6) facies are sometimes interbedded in these coastal plain clays. These facies correspond to very-coarse- to medium- grained sands organized in fining-upward sequences (several meters thick) with 2D and 3D current megaripple cross-beddings. The base of these sandy units is sharp and erosional and sometimes topped by thin intervals of pebbly to conglomeratic sandstones (lag).

The fining-upward trend within the cross-bedded sands is characteristic of distributary fluvial channels in an alluvial plain (e.g. Allen, 1965; Miall, 2006).

The channel well-log signature consists of low radioactivity values showing bell shapes (fining-upward trend) and a rapid shift of the gamma values at the base (Fig. 4).

4.1.2. Paleo-bathymetry

The absence of turbidite and hyperpicnal flows suggests a quite flat domain with no major slopes and thus a quite shallow lake, not very different from the present-day one (average depth of 25m; e.g. Howard and Karundu, 1992). This is supported by the rare occurrence of clinoforms on the seismic lines and the parallel and continuous configuration of the seismic reflector along which the facies evolves from distal lacustrine to coastal plain environments. The clinoforms are not higher than 100m.

4.1.3. Sequence stratigraphy analysis: basin-scale correlations

Five major cycles with a mean duration of 2 to 5 Ma (3rd order; Figs. 5 & 6) were identified and correlated on both the outcrops and wells based on the facies variation defined above. Numerous cycles of shorter duration (4th to 5th orders) were identified offshore and correlated from well to well with respect to their stacking pattern (Fig. 5).

Cycle 1 ($S1_{un} - S1_r$) is a highly asymmetrical cycle; its transgressive trend is locally recorded as the transition from a 0-2m thick poorly-sorted conglomerate overlying a weathered basement to lacustrine facies. The regressive half-cycle corresponds to the shift from mouth bars (Fa3) to coastal plain (lignitic clays, Fa5) and alluvial facies (distributary channel, Fa6; $S1_r$ MRS).

Cycle 2 ($S1_r$ to $S2_r$) is one of the most lacustrine-dominated cycles (with cycle 3, C3) as indicated by the distal clays (Fa1) which are characterized by large amount of organic material and intervals that are very rich in *Botryococcus* algae, illustrating the maximum flooding ($S2_m$). The regressive trend is characterized by the transition from flood deposits (alternating clays and sandy sheet-floods, Fa2) to the mouth bar (Fa3) where the MRS is positioned ($S2_r$).

Cycle 3 ($S2_r$ to $S3_r$) is the most lacustrine cycle. It is dominated by clays (with *Botryococcus* and organic material) and heterolithic clay-sand alternations (flood lobes). The regressive trend is characterized by a major unconformity ($S3_{un}$) coeval with a sharp facies transition from distal lacustrine deposits (Fa1) to proximal mouth bars (Fa3) and alluvial deposits (Fa5 and Fa6; $S3_r$ MRS). This transition is concomitant with a change in algae species from *Botryococcus* to *Pediastrum* and an increase in *Poaceae* pollens.

Cycle 4 ($S3_r$ to $S4_{un2}$) shows all the facies from the distal lacustrine (Fa1) to deltaic sheet-flood (Fa2 and Fa3), coastal plain (Fa5) and alluvial plain environments (Fa6). The lack of a significant amount of *Botryococcus* indicates that the most lacustrine facies ($S4_m$) are not as distal and "deep" as cycles 2 and 3. The regressive half-cycle is characterized by two 4th order unconformities ($S4_{un1}$ and $S4_{un2}$), the most important being the youngest one ($S4_{un2}$). It records a sharp transition from distal lacustrine to lacustrine shoreline (Fa4) and alluvial plain environments (fining-upward sequences; Fa6).

Cycle 5 ($S4_{un2}$ to the present day) is dominated by aerial alluvial deposits with *Poaceae* and *Podocarpus* pollens, this latter species being characteristic of high elevations. The maximum flooding ($S5_m$) is located in shallow lacustrine clays with an instant increase in *Botryococcus* and *Pediastrum* algae.

4.2. AGE MODEL

Several attempts to date sediments using fauna (mollusks, vertebrates) were made from the 1920's to the 1970's on isolated outcrops of the Kisegi-Nyabusosi and Kaiso-Tonya areas (e.g. Adam and Lepersonne, 1959; Bishop, 1971, 1965; Cooke and Coryndon, 1970; Gautier, 1965; Hooijer et al., 1963; Hopwood, 1926; Hopwood and Lepersonne, 1953; Lepersonne, 1949; MacInnes, 1942; Wayland, 1926). Nevertheless, the first dating based on a clear lithostratigraphy nomenclature was proposed by the Uganda Palaeontology Expedition at the turnaround of 1980's/1990's (e.g. Pickford et al., 1993).

Vertebrates are only preserved in the Kisegi-Nyabusosi area (Fig. 2), south of Lake Albert, where six formations were dated (Kisegi, Kakara, Oluka, Nyaburogo, Nyakabingo, Nyabusosi Formation; Fig. 6) and in the Kaiso-Tonya area (Fig. 3), on the eastern shore of Lake Albert where four formations were defined (Nkondo, Warwire, Kyeoro and Kaiso-Village Formations) (Pickford et al., 1993).

Located on the Congolese side of the rift (Sinda and Karugamania sites; Pickford et al., 1993; Yasui et al., 1992), the oldest sediments are Early Miocene in age as illustrated by the presence of *Deinotherium hobieyi* and *Brachyodus aequatorialis*. On the Ugandan side, the first sediments are dated at the second-half of the Middle Miocene (Kasande Member, upper part of the Kisegi Formation, 12.5 Ma) by vertebrate fossils including *Pleidon moharensis* as well as a small *Rhinocerotidae paradicerus mukirii*. The Late Miocene is characterized by the Kakara (11.5 – 9.0 Ma) and Oluka (6.5 - 5.0 Ma) formations whose the most characteristic fossils are *Tetralophodon anthracothere*, *Stegotetrabelodon*, *Primelephas gomphotheroides*, *Nyanzachoerus syrticus*. The Early Pliocene corresponds to the Nyaburogo Formation (4.2 – 5.0 Ma) in the Kisegi-Nyabusosi area and to the Nkondo (5.1 - 4.6 Ma) and Warwire ($\approx$ 4 Ma) Formations in the Kaiso-Tonya area. This time interval is characterized by numerous vertebrates including *Mammuthus subplanifrons*, *Torolutra ougensis* or different species of *Nyanzachoerus*. The Nyakabingo Formation of the Kisegi-Nyabusosi area and the Kyeoro (4.6-2 Ma) and Kaiso-Village ($\approx$ 2.2 Ma) Formations of the Kaiso Tonya area correspond to the Upper Pliocene with vertebrates including species of *Loxodonta*, *Elephas*,

Kolpochoerus or *Giraffa*. The transition between the Pliocene and Pleistocene is associated with the Nyabusosi Formation (≈ 1.5 Ma), in which examples of *Elephas recki atavus* or *Kolpochoerus majus* were found. Notice that several time intervals were not covered by the life range of the vertebrate fossils found in the outcropping areas (e.g. 0.6 Ma between the Kisegi and Kakara formations or 2.5 Ma between the Kakara and Oluka formations; Fig. 6).

The propagation of the proposed age model in the subsurface requires a climatic chart based on the correlation of the outcrops of the Kisegi-Nyabusosi and Kaiso-Tonya areas dated by vertebrates and subsurface data where a complete palynomorph record exists.

From the outcrops to the wells, five main stratigraphic 3rd order cycles were correlated. In addition, the 4th and 5th order cycles were correlated offshore with respect to their stacking patterns (Figs. 5 & 6). The first 3rd order cycle (C1, Lower Kisegi Formation – Early Miocene) corresponds to a relatively humid period as illustrated by a significant amount of *Pediastrum*. The second cycle (C2, Upper Kisegi Formation to Lower Kara Formation – Uppermost Early Miocene to the first half of the Upper Miocene) shows a major flooding highlighted by a peak of *Botryococcus* algae both on the outcrops and wells (S2_m MFS). The third cycle (Upper Kakara Formation to Oluka Formation - Late Miocene) is the most humid, with a significant amount of *Pediastrum* and *Botryococcus* and rare *Poaceae*. A peak of *Botryococcus* emphasized a second major flooding (S3_m) while the instant appearance of *Poaceae* is associated with the S3_{Un} unconformity. The 4th cycle (C4, Nyaburogo and Nyakabingo Formations – Pliocene) records an overall aridification highlighted by an increase in *Poaceae* and the transition from distal to coastal lacustrine environments. Unconformities (S4_{Un1} and S4_{Un2}) are associated with the disappearance of *Pediastrum* in favor of *Poaceae*. The last cycle (C5, Nyabusosi Formation – Pleistocene) marks the return of a more humid climate, as suggested by the increase in *Botryococcus* and *Pediastrum*.

This climatic signal of the Lake Albert Basin based on algae, pollen and spore trends is in good agreement with the regional climatic chart published by Bonnefille (2010) (Fig. 6). The maximum lake extensions interpreted from the significant amounts of *Botryococcus* (S2_m, Cycle C2 MFS; S3_m, Cycle

C3 MFS; S5_m, Cycle C5 MFS) are associated with large-scale tree coverage in Africa (humid period of Bonnefille, 2010) while the increase in *Poaceae* observed close to the S3_{Un}, S4_{Un1} and S4_{Un2} unconformities are coeval with arid periods (savannah or glaciation, Bonnefille, 2010; Fig. 6). This comparison is also a way to clarify the dating of the turnaround surfaces using the time range of the humid and arid periods as the interval of occurrence of MFS and MRS.

4.3. ACCOMMODATION EVOLUTION

Both the cumulative accommodation space and accommodation rates were measured for seven time lines (S1_{Un}, S2_m, S3_m, S3_{Un}, S4_m, S4_{Un1} and S4_{Un2}) using an average compaction hypothesis (Fig. 7). The variation in both the trends and rates is broadly the same regardless of which well is considered, with maximum rates around the Miocene-Pliocene boundary. The accommodation curves show three major periods bounded by two major unconformities (S3_{Un}, 6.2 Ma and S4_{Un2}, 2.7 Ma; Fig. 7).

Time interval 1 (S1_{Un} – S3_{Un}): Early (17.0 ± 0.8 Ma) to Middle (6.2 ± 0.2 Ma) Miocene: with mean values of 150 to 200 m/Ma, the rate of accommodation space creation is the slowest of the basin history. The sediment accumulation is located in the southern half of the basin and accommodation increases southward, with the cumulated accommodation ranging from 500m (wells 3 to 5; central part) to more than 2500m (wells 1, 2, and B; southern to central part). This time interval is subdivided in two sub-periods: (1) the S1_{Un} – S2_m (17.0 ± 0.8 Ma to 12.4 ± 0.4 Ma) interval shows moderate accommodation rates (<300 m/Ma, except in well B) while (2) the S2_m – S3_{Un} (12.4 ± 0.4 Ma to 6.2 ± 0.2 Ma) interval highlights a significant decrease from ≈ 250 m/Ma to 125 m/Ma in the most subsiding parts of the basin (wells A and B).

Time interval 2 (S3_{Un} – S4_{Un2}): Middle Miocene (6.2 ± 0.2 Ma) to Uppermost Pliocene (2.7 ± 0.2 Ma): the S3_{Un} unconformity marks a sharp increase in the accommodation rates in the whole basin with mean values higher than 500 m/Ma. In the most subsiding areas (southern and central part of the Lake Albert Basin), the accommodation frequently exceeds 600-800 m/Ma. Exceptions are observed on the footwalls of the Butiaba and Semliki faults (Kaiso-Tonya and Semliki compartments) where the sediment thickness is thinner (wells 3 and 4, see below). The S4_{Un2} unconformity is coeval with a sharp decrease in the accommodation rates from 600-800 m/Ma to 100 m/Ma.

Time interval 3 ($S4_{Un2}$ – Lake-floor): Uppermost Pliocene (2.7 ± 0.2 Ma) to the Present Day: The mean accommodation rate is significantly decreasing from 450 m/Ma ($S4_{Un2}$; 2.7 ± 0.2 Ma) to 250 m/Ma (present day) in the most subsiding part of the basin (wells 1, 2, A and B). The erosion of the uplifted Kaiso-Tonya and northern Butiaba areas led to the infilling of their accommodation space during this time interval.

4.4. ACCOMMODATION DISTRIBUTION AND INFILLING GEOMETRY: ISOPACH MAPS AND REGIONAL SECTIONS

4.4.1. Main geometries and fault patterns*

The main characteristic of the Lake Albert Basin is the symmetrical graben geometry of the central segment. Both the thickness map and regional sections show that four major faults accommodate the sedimentation between the $N40^\circ$ to $N60^\circ$ striking, $80-70^\circ$ dipping bounding fault systems (Bunia fault on the Congolese side and Toro-Bunyoro and Tonya fault systems on the Ugandan side, Figs. 2 & 8). Parallel to the $N70^\circ$ dipping Toro-Bunyoro bounding fault system, the $N60^\circ$ striking, 60° dipping Butiaba fault delimitates the Kaiso-Tonya compartment (Fig. 9; section 4). In the south-eastern part of the basin, the $N80^\circ$ Semliki fault dips toward the NW at an angle of 50° and individualizes the Semliki compartment (Fig. 9a; section 2). These compartments predominantly exposed parallel reflectors with only slight unclear thinning of the infilling toward the major faults (Fig. 9). The sedimentation consists of predominantly tabular stacking of the sediments, showing thickness variations on each side of the major faults (e.g. Butiaba and Semliki fault; Fig. 9; sections 2, 4 and 5). Thickness variation are only observed along the axis of the rift (thinning toward the north, Figs. 8 & 9; sections a and b). In the central part of the basin, the Kaiso-Tonya flat constitutes a structurally complex relay-ramp zone where the $N40^\circ$ Tonya fault system and $N60^\circ$ Toro-Bunyoro fault system are overlapping (Fig. 8). Connected to the Kaiso-Tonya flat, the $N140^\circ$ - $N160^\circ$ Ngassa transverse fault subdivides the basin into two sets, the southern one being thicker than the northern one. A last major $N40^\circ$ striking, 40° dipping fault, the Rwenzori fault, is observed at the northern tip of the Rwenzori Mountains, south of Lake Albert (Figs. 8 & 9, section 2).

Displacements related to the major N40-60° fault family gradually die out in diffuse zones of deformation, the Butiaba and Semliki transfer fault zones (TFZ; Figs. 8 & 9). Essentially observed in the Butiaba TFZ, a secondary N20° fault group shows a relative short length and small throw and is connected to the N60° trending fault. These faults are responsible for the horst and graben configuration of this TFZ. This northern Butiaba TFZ, like the southern Semliki TFZ, exposed a complex highly faulted pattern (Fig. 9a-b, sections 6, 7, c, d) where several folded (pop-up like) structures and "ramp-and-relay shapes" of the fault planes are locally observed.

4.4.2. Deformation evolution

The seismic data exposed numerous onlapping terminations of the basal sediments on the basement unconformity ($S1_{Un}$) but the infilling does not present any obvious growth strata (structural wedges). "Pre-rift" structures are locally observed below the $S1_{Un}$. Mainly located to the south of Lake Albert, these "valley-like" structures are approximately 500m deep and 4 km wide and show an onlapping reflector but no growth strata (Fig. 9, section 3). Some of these structures are asymmetric and controlled by a fault on one of their sides.

From the early to upper Miocene (time interval 1; $S1_{Un} - S3_{Un}$), sedimentation occurs all over the basin with a maximum accommodation space creation in the southern part, between the N80° striking, 50° dipping Semliki transverse fault and the N140-N160° striking, 70°-60° dipping Ngassa fault. During this period (mostly between $S1_{Un}$ and $S2_m$) of moderate sedimentation rates (50 to 250 m/Ma), sharp thickness variations along the NE-SW (Butiaba fault) to ENE-WSW faults (Semliki TFZ) form tabular and roughly isopach compartments (Kaiso-Tonya and Semliki compartments, Fig. 8). The infilling is also thicker south of the Ngassa faults (Fig. 8; section a). During this time interval ($S1_{Un} - S3_{Un}$), the finite displacement on the basin base ($S1_{Un}$) ranges from 1000m to 1600m down the Butiaba fault (Fig. 9a, section 5), 1200m down the Rwenzori fault (Fig. 9a, section 1), 800m down the Semliki fault (Fig. 9a, section 2) and 1500m south of the Ngassa fault (Fig. 9b, section a).

The second time interval (time interval 2; $S3_{Un} - S4_{Un2}$) shows a sharp increase in the sedimentation rates in the whole basin (up to more than 600 m/Ma, Fig. 8). The accommodation space creation migrates northward, beyond the Ngassa fault. Several depocenters (thickness > 1600m; Fig. 8) are

individualized (1) to the north-west of the basin, down the SW-NE Butiaba fault, (2) in the central part, down the N140° Ngassa fault and (3) to the west of the N40° Rwenzori fault in the southern corner of the basin (Fig. 8).

During this period ($S3_{Un} - S4_{Un2}$), the finite displacement on surface $S3_{Un}$ ranges from 500m to 800m west of the Rwenzori and Semliki faults, 800 to 1000m down the Butiaba fault and around 500m south of the Ngassa fault. The infilling consists of a thick isopach interval (up to 2000m, Fig. 9) characterized by a configuration of parallel reflectors. $S4_{Un1} - S4_{Un2}$ interval is locally marked by discrete differential accommodation and localized low stand wedges (Fig. 9; sections 5, b and c).

The Pleistocene (time interval 3; $S4_{Un2} - \text{Lake-floor}$) shows an overall trend of sediment thickening toward the central part of the basin (up to 1500m; Fig. 8) with the individualization of a major depocenter located down the Butiaba fault. The thickness distribution highlights erosion on the Kaiso-Tonya flat and in the northern termination of the basin. Another area of maximum accommodation space creation is located west of the Rwenzori fault (1500m, Fig. 8). Compared to the second time interval, the sedimentation rates decrease uniformly in the whole basin (from 500-600 m/Ma to less than 300 m/Ma; Fig. 8).

During this period, the fault throw gradually dies out. The finite displacement decreases in the whole basin and rarely exceeds 300m. The seismic quality associated with this interval is poor. However, the differential subsidence is highlighted by some unclear low stand wedges and the Pleistocene series are onlapping the $S4_{Un2}$ unconformity in the northern uplifted part of the basin (Butiaba area, Fig. 9, sections a and b).

4.5. ALBERT RIFT EVOLUTION

The Lake Albert Basin evolution can be subdivided into four major stages: a "pre-rifting" period and three "syn-rift" stages. Their characteristics are summarized on the Figure 10.

4.5.1.Pre-Rift (? to 17.0 ± 0.8 Ma, $S1_{un}$)

The first sediments are deposited on the weathering basement or filling incised "valley-like" structures (§4.4.2). The age and origin of these incisions are debated. Three scenarios can be proposed based on regional geological knowledge:

- (1) Carboniferous to Early Permian (Karoo) glacial incisions filled by post-glacial lacustrine sediments (Ecca-type facies). This scenario is supported by numerous evidences of glacial valleys on the Congolese side of the EARS described by several authors (e.g. Cahen and Lepersonne, 1981; Linol et al., 2015) since the work of Boutakoff (1948), and by the occurrence of Early Permian glacio-lacustrine sediments north of Lake Victoria (Entebbe area; Schlueter et al., 1993). In this scenario, these glacial valleys were later faulted during the Triassic extension, a widespread episode of deformation well known in eastern and southern Africa (e.g. Catuneanu et al., 2005).
- (2) A fluvial origin (bedrock channels) recording a pre-rift drainage flowing toward the Atlantic Ocean, as suggested by de Heinzelin (1962) and later by other authors (e.g. Pickford et al., 1993). The age of this network is not properly known but should be older than the Early Miocene and not the Pliocene as suggested by de Heinzelin (1962).
- (3) Structures controlled by normal faults during the earliest stage of the rift as supported by the occurrence of the first extensional geometries ($S1_{un}$ - $S2_m$) in the same area (south of Lake Albert).

The weathering profile (laterite) corresponds to kaolinitized basement rocks (5 to 20m thick in several wells). These laterite profiles are well known on both sides of the rift and are related to African-scale climatic events (Beauvais et al., 2008; Burke and Gunnell, 2008; Chardon et al., 2006). They were first described in Uganda by Ollier (1960) and characterized at the Ugandan scale by McFarlane (1976) and Taylor and Howard (1998). On the Congolese side, they are dated as Paleocene - Early Eocene using cross-cutting relationships with the volcanic rocks of the Cameroon Volcanic Line (Guillocheau et al., 2015). These ages are consistent with the absolute dating performed in West-

Africa by Beauvais et al. (2008). These weathering profiles are associated with humid periods recorded around the Early Eocene Climatic Optimum.

4.5.2. Uppermost Early Miocene To Late Miocene (17.0 ± 0.8 Ma to 6.2 ± 0.2 Ma; $S1_{Un}$ -

$S3_{Un}$): low extension phase

The first sediments are preferentially located south of the Ngassa fault where up to 2300m of accommodation space is created according to a mean rate of 150-250 m/Ma. In the early times (time interval 1a; $S1_{Un}$ - $S2_m$), the accommodation is controlled by the fault in the southern Lake Albert Basin, as illustrated by the moderate thickness variations on each side of the major faults (e.g. Rwenzori fault; Figs. 8 & 9).

The sedimentary infilling (cycles C1, C2 and transgressive half-cycle C3; Fig. 6) consists of lacustrine deposits (from distal "deep" facies to deltaic mouth bars and flood lobes), sometimes with fluvial deposits that are only observed on the Kaiso-Tonya flat and in the northern Butiaba (Fig. 8) and associated with the MRS. The C2 and C3 transgressive half cycles correspond to two major organic matter-rich lacustrine floodings (Fig. 6).

The main remaining questions are (1) the tectonic nature of the basin at this time (rift vs. flexural basin) and (2) its geographical extension compared to the present-day Lake Albert, with a larger lake at the time of deposition that later collapsed at the time of the true rifting.

- (1) The main depocenter locations (Fig. 8, time interval 1) are not clearly controlled by the faults, suggesting a flexural deformation regime rather than a pure extension controlled by the major bounding faults. This is supported by the low accommodation rate during this time interval which ranges from 125 m/Ma to no more than 250 m/Ma.
- (2) The arguments for a larger basin extension than the present fault bounding the Lake Albert rift are:
 - a northern large flexure, as stated above, suggesting a possibly larger basin than the present-day Lake Albert;
 - the presence of lacustrine distal facies at the time of the major lake flooding close to the present-day bounding faults (Toro-Bunyoro fault, Figs. 2 & 8), along the Kaiso-Tonya flat

(well 3 and well 4; Fig. 3), indicating a shoreline located beyond the present-day bounding faults;

- the absence of a true alluvial fan along the Kaiso-Tonya flat, close to the present-day border of the rift.

From a climatic point of view, this time interval records two humid periods, the second one corresponding to large-scale forest development recorded from Niger to East Africa and dated around 7 Ma (forest-phase; Bonnefille, 2010; Fig. 6).

These results question the age of the beginning of the sedimentary basin formation and of the initiation of the significant rifting. Previously, the rifting was considered as having initiated in the Uppermost Middle Miocene and Upper Miocene coeval with the initial Virunga volcanic episode (12.6 - 9 Ma, Kampunzu et al., 1998 and literature therein), following a "pre-rift" phase consisting of a shallow downwarp in Middle Miocene times (Pickford et al., 1993). Our work shows that sedimentation began as soon as the Uppermost Early Miocene (17.0 ± 0.8 Ma) in this downwarping (or flexure) which probably results from lithospheric stretching and thinning responsible for the local evidence of early and minor normal faulting observed in the infilling from the Uppermost Early Miocene (17.0 ± 0.8 Ma) to Late Miocene (6.2 ± 0.2 Ma).

4.5.3. Late Miocene To Lower Pleistocene (6.2 ± 0.2 Ma to 2.7 ± 0.2 Ma; S3_{Un}-S4_{Un2}): first rifting phase

The transition with the previous interval coincides with a sharp basin-scale unconformity (surface S3_{Un}). This time interval is characterized by a high accommodation rate (up to 800 m/Ma; Fig. 7) and the location of the main zones of subsidence are controlled by the faults (Fig. 8).

The sedimentary infilling (C3 regressive half-cycle and cycle C4; Fig. 6) mainly consists of distal shallow lacustrine facies passing laterally to deltaic and fluvial facies. Above the S4_m flooding, the progradational trend results from an infilling of the basin by littoral (Fa4) to fluvial (Fa5) deposits, coeval with a sand enrichment and an increase in *Poaceae* pollens (Fig. 6). The unconformities (S4_{Un1} and S4_{Un2}) are associated with the rapid disappearance of *Pediastrum* in favor of *Poacea* (Fig. 6).

The remaining question is the nature of the deformation regime, pure extensional or oblique. Some authors have previously argued for such an oblique extension on the basis of possible splay geometries of a few faults (negative and positive flower structures; Abeinomugisha and Kasande, 2012) and the obliquity of Lake Albert in the framework of the western branch (e.g. Abeinomugisha, 2003; Abeinomugisha and Kasande, 2012; Abeinomugisha and Mugisha, 2004; Delvaux and Barth, 2010; Logan et al., 2009). Nevertheless, our seismic interpretations (Fig. 9) do not highlight either the existence of clear flower structures (when looking at the 1:1 exaggeration scale) or an en echelon fault pattern, thus making it difficult to come to a conclusion about a possible major strike-slip component.

The high subsidence rates (600-800 m/Ma; Fig. 7) and the location of the depocenters down the major faults (Fig. 8) argue for a rifting phase. The lack of typical rift structures (e.g. growth strata and tilted blocks; Fig. 9) could be explained by the absence of shallow decollement levels.

4.5.4. Lower Pleistocene (2.7 ± 0.2 Ma, $S4_{Un2}$) to Present Say: second rifting phase

The transition to the last stage corresponds to a major unconformity ($S3_{Un2}$). Sedimentation occurred along two major depocenters located to the north-west, between the Bunia and Butiaba faults and to the south-west, down the Rwenzori fault. The mean accommodation rates decrease from 400 to 200 m/Ma (Fig. 8). The infilling ($C5$) is dominated by shallow lacustrine to fluvial deposits and the locations of the depocenters, combined with the subsidence rates, argue for a second rifting phase controlled by normal faults (Fig. 8).

The basal unconformity ($S3_{Un2}$) is related to the uplift of the Rwenzori Mountains and, probably, the Blue Mountains as indicated by:

- (1) the field mapping and paleontological dating of the sedimentary succession of the Kisegi-Nyabusosi area (Pickford et al., 1993), which indicates tilting and truncation at this time;
- (2) the thermochronological data (Bauer et al., 2016, 2015, 2012, 2010a; MacPhee, 2006) showing a major exhumation phase for the Rwenzori Mountains at the Pliocene-Pleistocene interface;
- (3) the occurrence of *Podocarpus* pollen which develop at an elevation higher than 1000m, confirming the growth of a close relief (i.e. the Rwenzori and Blue Mountains).

These vertical movements are coeval with the uplift of the present-day flats (or terraces; e.g. Kaiso-Tonya) bounded by the Butiaba and Toro-Bunyoro faults and the uplift and tilting of the northeastern part of the rift, the Butiaba area.

The S4_{Un2} unconformity can also be correlated with a major phase of aridity that is well identified around 2.5 Ma (Bonnefille, 2010; Fig. 6).

During the Middle Pleistocene (≈ 400 Ka), a second period of deformation and relief creation occurred with the flexuration of the Tanzanian craton in response to the uplift of both the western branch (Bauer et al., 2015, 2012, 2010a, 2010b) and eastern branch of the East African Rift System (Gregory Rift and North Tanzanian Divergence; Baker et al., 1978; Fairhead et al., 1972; Foster et al., 1997; Le Gall et al., 2008). This corresponds to a major drainage inversion and the creation of the Lake Victoria local base level (Pickford et al., 1993; Talbot and Williams, 2009; Taylor and Howard, 1998; Williams et al., 2003). This could be the growth period for the present-day Ugandan escarpment of the Albert Rift with reactivation of the Toro-Bunyoro and Tonya bounding faults, as suggested by the perched incised valleys observed at the top of the scarp.

5. DISCUSSION

The question here is whether to discuss the local- or EARS-scale meaning of the periods of deformation pattern changes in the Lake Albert Basin around 17.0, 6.2 and 2.7 Ma. From this perspective, we have summarized the evolution of the different basins in the EARS based on the tremendous amount of publications that have focused, per basin, on (1) the dated volcanism, (2) the sedimentary succession, (3) the known unconformities recording changes of deformation and (4) the denudation periods provided by the thermochronological data (Fig. 11). Unfortunately, no absolute ages are available for two major non volcanic rifts, the Tanganyika and Malawi Rifts.

5.1. UPPERMOST EARLY MIOCENE (17.0 Ma)

The first period dated at 17.0 Ma (late Early Miocene), i.e. initiation of the subsidence in the Lake Albert Basin – low and diffuse extension), is recorded on the northern part of the East African Dome along the eastern branch of the EARS in central and southern Kenya and in the Anza Rift. This is not

the case in the northern Kenya rifts (Turkana *s.l.*), on the gap between the Ethiopian and East African Domes, where it is not recognized.

In the Anza Rift (Morley et al., 1999a), this corresponds to the end of the subsidence of the basin under a strike-slip tectonic regime characterized by a major unconformity and the last marine flooding in the area.

In central Kenya (South-Kerio and Baringo-Bongoria basins), the Uppermost Early Miocene is associated with the end of a first depositional period of unknown age which possibly filled a first graben (Kimwarer and Kamego Formations; e.g. Chapman and Brook, 1978; Hautot et al., 2000; Tiercelin et al., 2012) overlapped by volcanics (Elgayo and Samburu basalt, Uasin-Gishu, Sidekh and Tim phonolites) onlapping both sides of the previous early sedimentary basin with a clear flexural pattern (Baker, 1987; Chapman and Brook, 1978; Hautot et al., 2000; Mugisha et al., 1997). This period is also coeval with the first occurrence of volcanism (Kishalduga nephelinites; ≈ 16 Ma) in southern Kenya, in the area of the Upper Miocene Gregory Rift (Crossley, 1979; Crossley and Knight, 1981).

5.2. LATE MIOCENE (6.2 Ma)

The initiation of significant rifting at 6.2 Ma (Late Miocene) in the Lake Albert Basin (Rift stage 1) can be related to a set of deformation events ranging from 7.5 to 6 Ma (with a lot of dating uncertainties) on the East African Dome, from the northern Kenya basins to the northern Tanzania basins, along the eastern branch and up to the Rukwa Rift in the central part the western branch.

In the northern Kenya basins, this period corresponds to the beginning of the outpouring of the Gombe Basalt which follows a hiatus of 6 Ma in both the volcanic and sedimentation record in the Koobi Fora Sub-basin (Nabwal Hills; north-east of the present-day Turkana Rift; McDougall and Watkins, 2006, 1988). This can also be the age of the discontinuity between the Nawata and Nachukui formations in the Lothagam area (south-west of the present-day Turkana Rift; McDougall and Feibel, 1999). In the central Kenyan Rifts, this period of deformation could be recorded by the unconformity occurring at the base of the Kabernet Trachyte in the Tugen hills (Chapman et al., 1978; Chapman and Brook,

1978). In the Rukwa Rift, the Late Miocene could correspond to the beginning of a second period of rifting (Morley et al., 1999b; Roberts et al., 2012, 2010; Wescott et al., 1991).

In central Kenya, thermochronological data indicates the denudation and uplift of the rift flanks between 7 and 4 Ma on the eastern side and between 5 and 2 on the western side (Spiegel et al., 2007).

5.3. PLIOCENE-PLEISTOCENE TRANSITION (2.7 Ma)

The change in rifting mode in the Albert Rift recorded at 2.7 Ma (Pliocene-Pleistocene transition; coeval with the uplift of the Rwenzori Mountains), is not easy to relate to one precise deformation event occurring along the East African Dome because of the several tectonics pulse (and associated unconformities) and deformation pattern changes recorded in both the western and eastern branches.

It could be related to the reactivation of the rifting in the Baringo-Bongoria Rift in central Kenya (Chapman and Brook, 1978; Hautot et al., 2000; Le Gall et al., 2000; Morley et al., 1992) or to the different stages of extension recorded in the basins of the North Tanzanian Divergence (2.5 and 1.5 Ma, Natron, Manyara and Eyasi Basins; Foster et al., 1997; Le Gall et al., 2008)

Taking into account an error bar of ≈ 1 Ma, the main unconformities of the Lake Albert Basin seem to occur at the East African Dome scale, even if, at this moment, it is impossible to infer and characterize the regional deformation changes at the time of these unconformities. A second interesting result is that the basins of both branches experienced the same geometrical evolution from large basins with limited fault controls during the Late Miocene to narrow true rifting in the Late Pleistocene (northern Kenya basins: Evans, 2013; Central Kenya Basins: e.g. Chapman et al., 1978), in agreement with the volcanism distribution, which was large (width > 100 km) during Miocene times, narrower (width $\times 10$ km) from Late Pliocene to Pleistocene times and is today limited to narrow rifts (Baker and Wohlenberg, 1971).

CONCLUSIONS

In the present work, we have proposed a new reconstruction of the tectono-sedimentary evolution of the Lake Albert Basin based on a re-evaluation of the outcropping data (sedimentary facies and biostratigraphic data) and on an exceptional subsurface dataset. We were able to:

- carry out the first sequence stratigraphic framework for one of the East African Rifts (the Lake Albert Rift) defining the major stratigraphic surfaces (maximum flooding and unconformities) and cycles on the basis of outcrops, well-logs (stacking pattern) and pollen/spore trend (proxy of the lake level variations) correlations,
- propose an age model based on the onshore mammals biozones propagated at the basin-scale by onshore – offshore correlations and climatostratigraphy (palynology and sequence stratigraphy),
- quantify the accommodation (as a proxy of subsidence) evolution through time using all of the previously mentioned data.

On the basis of biostratigraphical studies, early deposition in the Lake Albert Basin occurred during Early Miocene times (17.0 Ma), much older than the Late Miocene age previously considered on the basis of volcanic events and old biostratigraphical ages.

The infilling essentially consists of lacustrine deposits wherein two major unconformities dated at 6.2 Ma (Uppermost Miocene) and 2.7 Ma (Pliocene-Pleistocene boundary) were characterized, coeval with major subsidence and climatic changes.

Combined with the fault analysis, the evolution of the subsidence and its distribution highlight a four-step evolution of the Lake Albert Basin:

- Incision of the basement of unknown origin and age but prior to the Early Miocene.
- 17.0 to 6.2 Ma: the flexural basin was potentially larger than the present-day rift and was infilled by organic-rich lacustrine deposits.

- 6.2 to 2.5 Ma: first phase of rifting characterized by high subsidence rates in depocenters controlled by the fault.
- 2.5 to 0 Ma: a second rifting phase following the uplift of the Rwenzori Mountains and, potentially, the Blue Mountains. The locations of the depocenters are controlled by the major faults and predominantly located in the central and southern part of the basin.

The specificity of the Lake Albert Basin is its geometrical configuration. Actually, it consists of isopach fault-bounded units with no clear characteristics of a rift (i.e. tilted blocks, growth strata) but with relatively high subsidence rates, possibly suggesting low extension rates and a lack of a shallow decollement level.

ACKNOWLEDGMENTS

We gratefully acknowledge current and former Total colleagues for their contributions to the global database used in this study. We are also grateful to Dr. Sara Mullin for post-editing the English and to the two reviewers for their constructive comments.

FUNDINGS

This work was supported by the Total company (Centre scientifique et technique Jean Feger, Pau, France).

FIGURE 1: (2 columns fitting image)

Figure 1: The East African Rift System and its western branch. Morphological and Cenozoic geological settings of the East African Rift System (Fig. 1a) and geological features of the western branch from the Archean (cratons) to Mesozoic (Karoo basins) and Cenozoic (East African rifts) (Fig. 1b). Faults and geological contours from Chorowicz (2005), Le Gall et al. (2000, 2004, 2005), McCarthy (2005) and the Tectonic map of Africa, Milesi et al. (2010).

FIGURE 2: (2 columns fitting image)

Figure 2: The Albertine Rift System. Geological and structural map of the Albertine Rift system from the Azwa lineament to the Virunga volcanic province. Geological contours, faults and structural lineaments modified after MacDonald and the Department of Geological Survey and Mines of Uganda, 1966 and GTK Consortium, Jenett et al. (2009).

FIGURE 3: (1.5 column fitting image)

Figure 3: Location map of the interpreted data. The wells and field-sections are localized onshore on the Ugandan side of the Lake Albert Basin. Wells 1 to 5 correspond to petroleum exploration wells while wells A and B are fictive wells interpreted from the seismic data.

FIGURE 4: (2 columns fitting image)

Figure 4: Main characteristics of the litho-facies associations. Main depositional environments, lithologies, palynomorph and well-log signatures of the five facies associations identified on the outcrops and wells.

FACIES ASSOCIATION 1 (Fa1): Distal "deep" lacustrine

Lithology and granulometry	Sedimentary structures	Bioturbation & biological content	Process of formation Interpretation	Well-logs facies signature
Homolithic and massive or horizontally laminated dark to light grey clays	Few ferruginous nodules and concretions; diagenetic gypsum	- Botryococcus algae - Rare in-situ freshwater bivalves - Organic-rich (carbonaceous)	- Decantation - Distal lake	<p>Cylindrical and homolithic to slightly silty heterolithic facies; high radioactivity (days)</p>

FACIES ASSOCIATION 2 (Fa2): Proximal "shallow" lacustrine

Lithology and granulometry	Sedimentary structures	Bioturbation & biological content	Process of formation Interpretation	Well-logs facies signature
- Alternation of grey clays, silty clays and thin beds (1-20cm) of fine to medium sands - Poorly sorted sands - Clay dominated	- Clays: massive or horizontally laminated - Sands: most of the time massive; rare unidirectional current ripples or megaripples cross-bedding, horizontal bedding	- Occasional vertical and/or horizontal burrows in sand - Most of the time monospecific; rare beds showing plurispecific bioturbations - Pedicellariae algae - Locally organic-rich	- Decantation perturbed by floods - Shallow lake	<p>High variations (thin peaks) of radioactivity (gamma-ray) and porosity values. Funnel shape of gamma-ray (coarsening upward trend)</p>

FACIES ASSOCIATION 3 (Fa3): Lacustrine delta

Lithology and granulometry	Sedimentary structures	Bioturbation & biological content	Process of formation Interpretation	Well-logs facies signature
- Fine- to coarse-grained sandstones; predominantly medium- grained (decimetric to plurimetric beds; 20cm - 2-3m) - Well sorted, occasional coarsening upward trend	(a) Current ripple and megaripple (3D) cross-bedding; decimetric set; localized reactivation surfaces and interbedded clays (b) Climbing ripple and megaripple and 3D/2D megaripples cross-bedding superimposed on sand bars -> (compound cross-bedding); (a) and (b): top of bed-set locally consisting of by-passing surface (pebble level)	- Occasional monospecific bioturbation (vertical burrows) - Pedicellariae algae in clayey interval	- Lacustrine delta: subaqueous distal mouth-bars	<p>Funnel shapes (coarsening up trend); sandy heterolithic facies. Sharp radioactive top (days)</p>

FACIES ASSOCIATION 4 (Fa4): Lacustrine shoreline

Lithology and granulometry	Sedimentary structures	Bioturbation & biological content	Process of formation Interpretation	Well-logs facies signature
- Massive fine- to medium-grained clean and well sorted sandstone (decimetric to metric beds)	- Current and avalanching ripple/megaripple cross-bedding	- Very bioturbated; horizontal and vertical burrows, plurispecific bioturbation - Local coquina (gastropods debris)	- Lacustrine shoreline - Lacustrine embayment	Similar to Fa2 electro-facies due to numerous interstratifications of clayey intervals (Fa1)

FACIES ASSOCIATION 5 (Fa5): Lacustrine coastal plain

Lithology and granulometry	Sedimentary structures	Bioturbation & biological content	Process of formation Interpretation	Well-logs facies signature
- Dark-grey to green massive clays, locally silty - Few hydromorphic soil	None	- Rare burrows (insect?) - Plant remains, lignite (cuticles, wood debris) - Poaceae, graminiae	- Decantation - Lacustrine coastal plain: marshes, ponds - Water saturation	<p>Bell and cylindrical shape; low density, high porosity and radioactivity (lignite and clays)</p>

FACIES ASSOCIATION 6 (Fa6): River channel

Lithology and granulometry	Sedimentary structures	Bioturbation & biological content	Process of formation Interpretation	Well-logs facies signature
- Very coarse- to medium-grained reddish sandstones (decimetric to plurimetric beds) - Relatively well sorted; fining upward trend	- Megaripples (2D) cross-bedding in decimetric laminasets - Sharp end/or erosional base - Occasional basal conglomeratic lag	Rare burrows (insect?)	- Bedload - Distributary channel of a lacustrine delta - Alluvial plain	<p>Bell shape with sharp base (fining -up trend)</p>

FIGURE 5: (2 columns fitting image, landscape orientation)

Figure 5: Basin-scale correlations. Examples of correlated wells along the Lake Albert Basin. Correlations were performed with respect to the sequence stratigraphy method and paleo-environmental data (palynomorph, example in Figure 6 for well 1). The locations of the wells and outcrops are given in Figure 3.

FIGURE 6: (2 columns fitting image, landscape orientation)

Figure 6: Age model of the Lake Albert Basin sedimentary infilling. Ages of the seven stratigraphic surfaces interpreted from field and subsurface analyses. The biostratigraphic ages are compared to the paleo-environmental (paleomorph; Total, pers. comm.) and regional climatic chart (Bonnefille, 2010).

FIGURE 7: (2 columns fitting image)

Figure 7: Accommodation and associated accommodation rate evolution of the Lake Albert Basin. The accommodation is measured using the backstripping method on five exploration wells (wells 1 to 5) and two fictive wells (wells A and B) interpreted from the seismic data. See Figure 3 for the location of the wells.

FIGURE 8: (2 columns fitting image)

Figure 10: Synthetic chart of the Lake Albert Basin evolution. Climatic chart from Bonnefille (2010) and ages of the volcanic episodes in the western branch from Ppuclet et al. (2016) and Kampunzu et al. (1998; and literature therein).

FIGURE 11: (2 columns fitting image; landscape orientation)

Figure 11: Synthetic chart of the initiation and main stages of evolution of the rift basins of the western and eastern branches of the East-African Rift System based on the age of their sedimentary and volcanic infilling (based on a bibliographic synthesis, references in the figure).

RESEARCH HIGHLIGHTS

- Early deposition in the Lake Albert Basin occurred during Early Miocene times (17 Ma), much older than the Late Miocene age previously mentioned.
- The sedimentary infilling essentially consists of sub-aquatic lacustrine deposits wherein major unconformities related to subsidence and climatic changes were characterized.
- The Lake Albert Rift evolution consists of three major steps: (1) low and diffuse extension from 17.0 to 6.2 Ma, (2) first phase of rifting from 6.2 to 2.5 Ma and (4) second rifting phase and uplift of rift shoulder from 2.5 and 0 Ma.
