**Abstract** Hubble Space Telescope (HST) observations of the Martian hydrogen exosphere in Lyman  $\alpha$  are presented in this paper for a period when Mars passed perihelion and southern summer solstice in its orbit. The peak intensity in the exospheric Lyman  $\alpha$  brightness was recorded after Mars went past its perihelion, slightly after southern summer solstice. The increase in brightness as Mars approached perihelion was found to not be symmetric around the peak, making it impossible to fit the H escape flux trend with a single sinusoidal curve with the peak at perihelion. While the short-term ( $\sim 30$  Earth days) changes were not directly correlated with changes in the solar Lyman  $\alpha$  flux, the long-term ( $\sim 10$  Earth years) trend in the data does show some correlation with solar activity. This suggests that the short-term changes brought about in the exosphere could be due to intrinsic changes occurring within the lower atmosphere. For example, thermospheric heating by dust can alter the cold-trapping mechanism for water vapor resulting in it being present in large quantities at higher altitudes (60–80 km), possibly enhancing the escape flux of H. Therefore, it is important to understand the drivers of atmospheric dynamics in the Martian atmosphere, which produce the yearly enhanced seasonal changes observed at Mars around periapsis and southern summer solstice in order to accurately determine the total amount of water lost over its history.

## 1. Introduction

The Martian hydrogen exosphere is much more dynamic than was thought after the era of Mariner exploration in the early 1970s (Bhattacharyya et al., 2015; Chaffin et al., 2014; Clarke et al., 2014). Seasonal changes in the escape of hydrogen from Mars have been discovered in the last decade, adding another dimension to reconstructing the timeline of water escape through Mars' history of evolution. It is imperative to understand the underlying factors triggering the seasonal trends observed in the hydrogen escape flux to determine the total amount of water on Mars nearly 4.2 billion years ago. Tracing the history of water on Mars would help understand the conditions required to sustain the presence of liquid water on planets in general.

Hunten (1973) first calculated that the escape of hydrogen atoms from the Martian exobase (altitude  $\sim 200$  km) is diffusion limited. In this view the density of hydrogen at the exobase adjusts such that the escape flux from the exobase is consistent with the upward flux from lower altitudes. Krasnopolsky (2002) combined this theoretical interpretation with the fact that most of the H is transported into the exosphere from lower altitudes in the form of  $H_2$ , which has a slow diffusion rate as well as a longer lifetime, to suggest that the escape flux of H from the atmosphere of Mars should almost be a constant, without much seasonal variation. Therefore, once this "constant" number has been determined it could be used to extrapolate back in time to calculate the total amount of water that Mars has lost over time.

Observations of Mars conducted in the past decade to constrain H escape found that the theoretical scenario of a constant escape flux of H from Mars is no longer valid (Bhattacharyya et al., 2015; Chaffin et al., 2014; Clarke et al., 2014). The first reported observations of Mars that disproved the diffusion-limited flux scenario were conducted by the Hubble Space Telescope (HST) in the far ultraviolet (FUV) during October–November 2007, during which a  $\sim 40\%$  decrease in Lyman  $\alpha$  brightness was seen within a period of  $\sim 4$  weeks (Clarke et al., 2009, 2014). The Lyman  $\alpha$  emission consists of solar photons resonantly scattered by the H atoms present in the exosphere of Mars. Over a longer period (July–December 2007) overlapping with the HST observations, the SPICAM instrument on board Mars Express (MEX) also observed a steady decrease in Lyman  $\alpha$  brightness from the exosphere of Mars (Chaffin et al., 2014). It was difficult to distinguish if this observed

change in Lyman  $\alpha$  brightness from the Martian exosphere was a result of seasonal changes or changes in the atmospheric temperature and density due to a global dust storm that took place in June 2007. Further modeling efforts and more HST observations conducted in the year 2014 pointed toward the trends being seasonal in nature (Bhattacharyya et al., 2015; Chaufray et al., 2015).

At present multiple direct and indirect observations of the hydrogen population present in the exosphere of Mars have found density changes associated with seasonal effects. The Ion Mass Analyzer on MEX found the distribution of pickup ions outside the bow shock to be quite different between perihelion and aphelion of Mars' orbit (Yamauchi et al., 2015). Analysis of pickup ions measured by the Solar Wind Ion Analyzer (SWIA) and Supra-Thermal and Thermal Ion Composition instruments on board the Mars Atmosphere and Volatile Evolution (MAVEN) spacecraft revealed an order magnitude change in the neutral hydrogen density profile with seasons (Rahmati et al., 2017). Halekas et al. (2017) also found an order of magnitude seasonal change in exospheric hydrogen column density by analyzing SWIA measured penetrating protons. Other observations of proton cyclotron waves excited by hydrogen pickup ions upstream from Mars by the magnetometer and their relationship with the solar extreme ultraviolet (EUV) flux measured by the Extreme Ultraviolet Monitor (EUVM) on board MAVEN show higher occurrence rates when Mars is close to perihelion than at other times of the year (Romanelli et al., 2016). Direct observations of the Lyman  $\alpha$  emission by the IUVS on board MAVEN both in the FUV imaging mode and the echelle mode (Mayyasi et al., 2017; McClintock et al., 2015) also showed substantial temporal and spatial variability as Mars moved around the Sun (Chaffin et al., 2015; Clarke et al., 2017).

Several models have been developed to chart out the seasonal variations in the hydrogen escape flux at Mars and to understand the contributing factors behind these observed changes. The optically thick Lyman  $\alpha$  emission measurements of the Martian hydrogen corona have been modeled using a radiative transfer model (Anderson & Hord, 1971; Bhattacharyya et al., 2017; Chaffin et al., 2014; Chaufray et al., 2008) in order to calculate the escape flux of H from Mars with seasons. Modeling the SPICAM observations taken over a period of 6 months in the later half of 2007 (July–December) revealed almost roughly an order magnitude decrease in hydrogen escape flux due to seasonal changes, as Mars moved away from the Sun (Chaffin et al., 2014). Similar changes were also observed with HST in 2014 when the hydrogen escape flux steadily increased in magnitude as Mars moved toward its perihelion position (Bhattacharyya et al., 2015). Simulations with the Mars Global Circulation Model from Laboratoire de Météorologie Dynamique (MGCM-LMD) concluded that changes in extreme ultraviolet (EUV) flux from the Sun due to changing Mars-Sun distance coupled with upper atmospheric dynamics would result in seasonal changes resembling a sinusoid in logarithmic space for the escape flux of H from Mars, with the peak at perihelion ( $L_s = 251^\circ$ ) (Chaufray et al., 2015). The MGCM-LMD model predicts seasonal changes of a factor of 5 due to EUV heating of the thermosphere. However, the variations in H escape flux predicted by the model were lower than that observed by HST in 2014 ( $L_s = 138^\circ$ – $232^\circ$ ) (Bhattacharyya et al., 2015), suggesting that changing EUV flux might not be the only contributor toward the observed seasonal behavior of H escape from Mars.

The substantial changes in Lyman intensity  $\alpha$  intensity observed over short period of time of  $\sim 1$  month by MEX, HST, and MAVEN have been thought to be associated with the presence of large amounts of water vapor at high altitudes, detected by Mars Express, especially when Mars is approaching perihelion and southern summer solstice (Fedorova et al., 2009; Maltagliati et al., 2013). The effect of introducing considerable amount of water vapor at high altitudes on the escape flux of H from the exosphere of Mars has been recently studied using a one-dimensional time-dependent photochemical model by Chaffin et al. (2017). They find that water vapor at high altitudes can produce a large increase in H escape rate on a time scale of weeks prompting the conclusion that H escape from Mars may be dominated by this process. The HST observations (Bhattacharyya et al., 2015), SPICAM observations (Chaufray et al., 2008), and MAVEN observations during orbit insertion (Chaffin et al., 2015) of the Martian exosphere also hinted at the possibility of the existence of a nonthermal population of hydrogen at Mars. This population seems to display a seasonal behavior, with increased density near perihelion (Bhattacharyya et al., 2017).

The observations of the Martian hydrogen exosphere conducted in the past decade do not cover the full range of the seasonal trend in hydrogen escape with numerous gaps in the temporal coverage over a Martian year. This makes it difficult to determine the total amount of water that has escaped from Mars, which is the main goal for studying Martian hydrogen escape. Therefore, it is essential to characterize the seasonal

behavior over different solar longitudes for different solar conditions to fully understand the factors that cause seasonal changes in the hydrogen corona at Mars. This, in turn, will help trace the timeline for water loss from Mars over its evolution history and allow a more accurate determination of total amount of water harbored by Mars ~4.2 billion years 160 ago.

In this paper we present HST observations of the Martian exosphere during a period when Mars passed perihelion ( $L_s = 251^\circ$ ) as well as southern summer solstice ( $L_s = 270^\circ$ ) in its orbit. Earlier observations with HST in 2014 indicated a steady increase in intensity as Mars approached perihelion, but there were no observations after  $L_s = 232^\circ$  to determine the time of peak intensity in the Lyman  $\alpha$  brightness of the Martian exosphere or the shape of the brightness curve with time. The current observations cover that gap in data as Mars passed perihelion and southern summer solstice coverage and provide an insight into the behavior of the Martian exosphere during this time. One advantage of using HST over Mars-orbiting satellites is that it presents a more comprehensive view of the global structure, with coverage up to altitudes of ~30,000 km favoring the study of the high-energy population dominant at the higher altitudes. We model the observations with a radiative transfer model (Bhattacharyya et al., 2017) in order to trace the hydrogen escape flux over this time period as Mars passed through the distance of closest approach to the Sun. Section 2 describes the observations presented in this paper. Section 3 briefly summarizes the modeling procedure. Section 4 discusses the results of the data analysis, and section 5 discusses the implications of the findings inferred from this dataset.

## 2. HST Observations of Mars

The Hubble Space Telescope's (HST) Advanced Camera for Surveys instrument was used to observe the Lyman  $\alpha$  emission from the hydrogen atoms present in the exosphere of Mars. These observations were conducted in a series of five separate visits starting in September 2016 and ending in January 2017. The gap between each pair of visits was ~1 month. During this time Mars moved from  $L_s \sim 226.3^\circ$  to  $302.1^\circ$  and the Earth-Mars distance varied from 1 AU to 1.76 AU. The details of the observations are listed in Table 1. With the Mars disc placed in one corner of the field of view, a large portion of the dayside exosphere was imaged during the HST observing campaign (Figure 1). An earlier observation of Mars conducted with HST on 3 December 2015 with Mars close to its aphelion position ( $L_s \sim 76.4^\circ$ ) has also been included in this paper. The HST data reduction process has been described extensively in earlier publications about studies of the Martian exosphere with the same type of HST data (Bhattacharyya et al., 2015, 2017; Clarke et al., 2014). The calibration factor used for the HST data presented in this paper is  $0.002633 \text{ counts pixel}^{-1} \text{ s}^{-1} \text{ kR}^{-1}$  for consistency with prior observations (Bhattacharyya et al., 2017). The main goal of these observations is to trace the seasonal behavior of the hydrogen exosphere as Mars passed perihelion ( $L_s \sim 251^\circ$ ) and southern summer solstice ( $L_s \sim 270^\circ$ ).

**Figure 1.** A reduced HST image of Mars taken on 19 January 2017, mapping the Lyman  $\alpha$  emission from the hydrogen atoms present in the exosphere of Mars. The Sun is located on the right in this image. The dark circle in the top left of the image is the disk of Mars. It appears noisy as the reduction method involves the difference of two filtered images, one that allows Lyman  $\alpha$  (121.567 nm) and one that does not. Since the disk of Mars has other emissions, the small difference between two large values results in noise at the disk. However, above  $1.2 R_{\text{mars}}$  all the emission is Lyman  $\alpha$ . The Lyman  $\alpha$  intensity profile from this image is created by averaging pixels at same radial distances within the  $\pm 45^\circ$  angle around the subsolar point as shown in this figure.

radiative transfer model (Bhattacharyya et al., 2017). The Lyman  $\alpha$  emission is optically thick and multiple scattering effects within the corona have to be accounted for in order to model the observed intensity accurately (Anderson, 1974; Anderson & Hord, 1971). Two types of models were used to simulate the data, one with only a single thermal population of hydrogen (one-component model) and another with a thermal and a super-

**Figure 2.** Radial intensity profiles of the Lyman  $\alpha$  emission with altitude for the exosphere of Mars. Notice that the brightness increase is not symmetric with time as seen in the overlapping intensity profiles observed at solar longitudes  $L_s = 226^\circ$  (20 September 2016) and  $L_s = 246^\circ$  (21 October 2016). The peak brightness is somewhere between  $L_s = 264^\circ$  (19 November 2016) and  $L_s = 302^\circ$  (19 January 2017), as indicated by the decrease in intensity after  $L_s = 283^\circ$  (19 December 2016). The observation at  $L_s = 76^\circ$  (3 December 2015) was conducted when Mars was close to its aphelion, just past northern summer solstice.

Figure 2 shows the radial intensity profiles of the Lyman  $\alpha$  emission with altitude of the Martian hydrogen exosphere. These profiles have been constructed by averaging all the pixels located at similar radial distances from the center of the planet over a range of  $\pm 45^\circ$  around the subsolar point (Figure 1). This angle of  $\pm 45^\circ$  has been chosen for good signal-to-noise ratio in the data. As is seen in Figure 2, the intensity increased and reached its peak value somewhere between November 2016 and January 2017. It should also be noted that the increase in intensity of the Lyman  $\alpha$  emission from the Martian exosphere was not symmetric about the maximum in time, as the intensity profile from the first two observations in 2016 (20 September and 21 October) lie almost on top of each other (Figure 2). There is also significant variation in the slope of the curves. For example, as shown in Figure 2, the slope of the intensity profile for 19 November 2016 is higher than the slope of the 19 December 2016. The difference between the two curves is much smaller at lower altitudes ( $< 5,000$  km) and gradually grows at higher altitudes ( $> 8,000$  km). The shape of the profile provides information about the thermal (dominant at lower altitudes) and the superthermal component (dominant at higher altitudes) and their density changes due to seasonal variations. It is highly likely that the superthermal population is a mixture of more than one Maxwellian or has a completely non-Maxwellian distribution altogether (Gröller et al., 2015; Shematovich, 2013).

### 3. Calculating the H Escape Flux at Mars

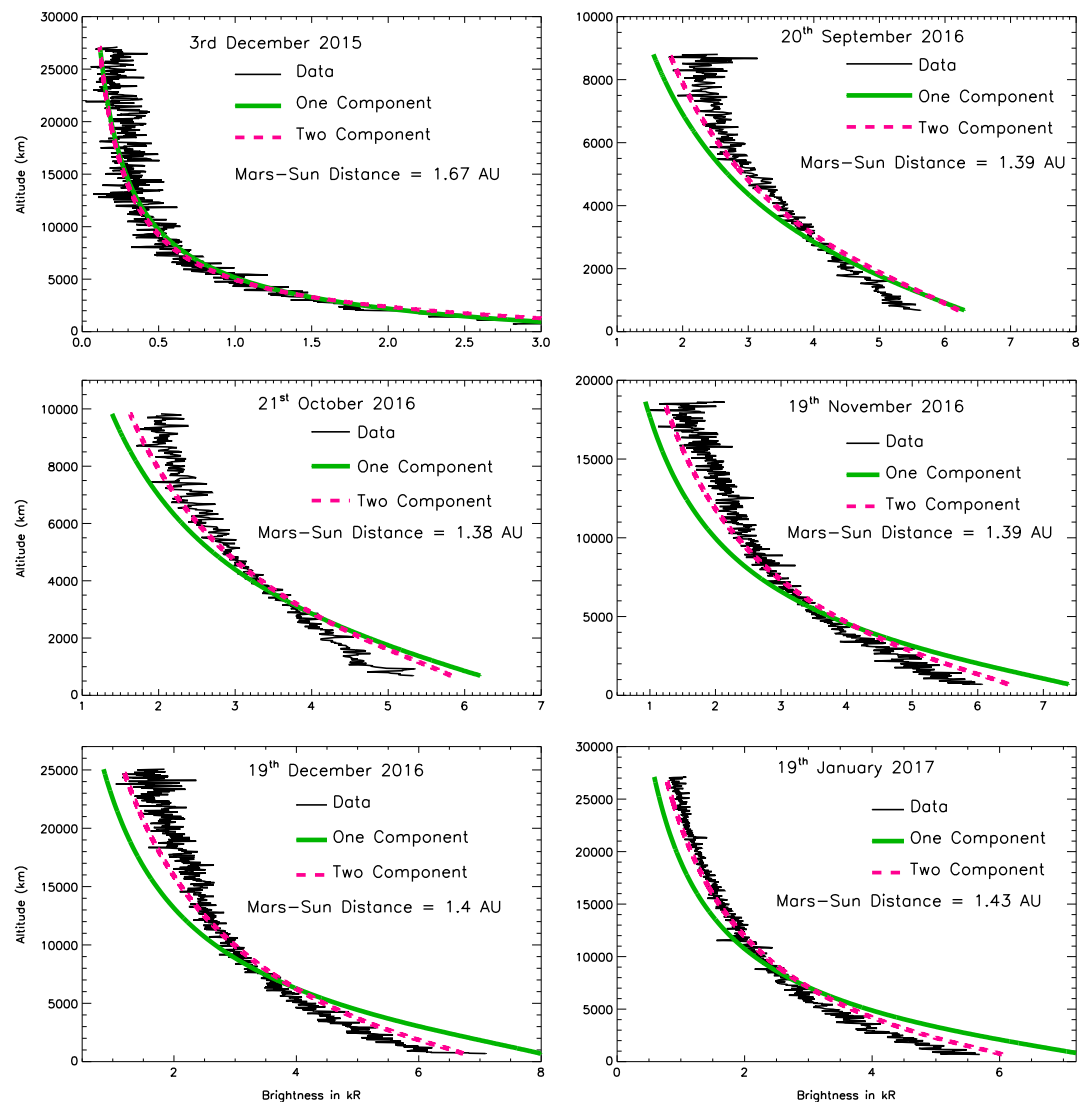

The intensity profiles of the Lyman  $\alpha$  emission from the distribution of hydrogen atoms in the Martian exosphere were modeled using a radiative transfer model (Bhattacharyya et al., 2017). The Lyman  $\alpha$  emission is optically thick and multiple scattering effects within the corona have to be accounted for in order to model the observed intensity accurately (Anderson, 1974; Anderson & Hord, 1971). Two types of models were used to simulate the data, one with only a single thermal population of hydrogen (one-component model) and another with a thermal and a superthermal population of hydrogen (two-component model) in the exosphere of Mars. These models have been discussed in detail in Bhattacharyya et al. (2015, 2017). The best fit model results to the data determined by minimizing  $\chi^2$  deviations between data and model, put constraints on the temperature and density of the hydrogen atoms at the exobase of Mars, taken to be at an altitude of 200 km in the model. These temperature and density values have then been used to calculate the Jeans escape flux of hydrogen, which is considered to be the primary process of escape for H from Mars (Hunten, 1973, 1982). The uncertainty in the hydrogen escape flux for each observation has been calculated by determining all the model runs that produce fits which lie within  $\chi^2_{\text{min}} + 1$ . The best fit temperature and density values for the most recent HST observations presented in this paper are listed in Table 2 along with the corresponding Jeans escape flux of H from the exobase of Mars in Table 1. Figure 3 shows the model fits to the HST data. As is seen in the figure, for the September, October, and the November 2016 data, both the one-component and the two-component models do not provide good fits. This is likely because the physics driving the superthermal population (Gröller et al., 2015; Shematovich, 2013) is not well represented within the model, which assumes a single Maxwellian distribution at a temperature of 800 K for the energetic atoms. This temperature of 800 K for the

**Table 2**

19 January 2017/019	1.592	440	55,000 ± 4,000	200	101,000 ± 12,000	32,400 ± 2,900

**Figure 3.** The best one-component and two-component model fits to the data for all the HST 2015–2017 observations. The model profiles lie almost on top of each other when Mars was far away from the Sun (3 December 2015). The two-component model does a better job fitting the data as Mars moved closer to the Sun but is unable to fit the data perfectly. This could be because there is more than one superthermal population, depending on the source processes that generate them with a non-Maxwellian velocity distribution. The model assumes a single Maxwellian distribution of 800 K for the nonthermal population, which is not a completely accurate description of the physics.

superthermal population has been chosen to maintain the consistency with the analysis of previous HST observations (Bhattacharyya et al., 2015, 2017), so that the seasonal trend in the escape flux of H could be established using the entire HST data set. This temperature is well within the range of possible temperatures derived for the superthermal population using Mars Express observations (Chaufray et al., 2008). More sophisticated fits to the hot component are being pursued outside the scope of this paper.

There are several factors that increase the uncertainty in determining the escape flux of H from Mars. These include the potential presence of a nonthermal population whose characteristics are unknown at this time and which is the largest contributor to the uncertainty in the H escape flux from Mars (Bhattacharyya et al., 2017), degeneracy between the temperature and density values obtained from the radiative transfer model (line of sight intensity can be increased by either increasing the number of scatterers, that is, density, or increasing the temperature of the population which scatters more of the solar Lyman  $\alpha$  line due to a broadened line profile) for both the thermal and the nonthermal population, uncertainty in the absolute calibration of the observing instrument, and various assumptions that have been made about the intrinsic characteristics of the Martian exosphere in the modeling process. These factors have been discussed in detail in Bhattacharyya et al. (2017), an analysis that is not repeated here. In this paper we focused on the trends in the data, which is significant enough to be detectable above the noise, and which will help us to better understand the driving forces behind the seasonal changes in the Martian hydrogen exosphere, as well as steer the direction of future modeling efforts.

#### 4. Variability of Hydrogen Escape From the Exosphere of Mars

The biggest motivation for studying hydrogen escape from the Martian exosphere is to determine the total amount of water lost by Mars throughout its history of evolution. One-dimensional (1-D) photochemical models show that most of the hydrogen present in the Martian corona comes from the photodissociation of water vapor near the surface of Mars (Hunten & McElroy, 1970; McElroy & Donahue, 1972; Parkinson & Hunten, 1972). These models predicted that the escape of H from the exosphere of Mars should be diffusion limited (Hunten, 1973; Krasnopolsky, 2002). However, seasonal variations in H escape were observed at Mars thereby disproving the diffusion-limited theory (Bhattacharyya et al., 2015; Chaffin et al., 2014; Clarke et al., 2014). It is important to characterize this seasonal behavior in H escape and understand the factors influencing it in order to accurately calculate the total amount of water lost from Mars.

The HST observations of the Martian corona presented in this paper have been helpful toward tracing the seasonal behavior of the hydrogen exosphere at Mars. These observations were conducted when Mars was moving between  $L_s \sim 226.3^\circ$  to  $302.1^\circ$  passing perihelion ( $L_s \sim 251^\circ$ ) and southern summer solstice ( $L_s \sim 270^\circ$ ), a section of the orbit which lacked coverage in the earlier data sets.

The HST observations show that the peak intensity in the Martian exospheric Lyman  $\alpha$  emission was achieved after southern summer solstice rather than at perihelion (Figure 2), a trend also mimicked by the hydrogen escape flux (Figure 4) determined from the single and the two-component analysis of the data. The peak in H escape flux was also observed to be around southern summer solstice using data from the SWIA instrument on board the MAVEN spacecraft (Halekas, 2017). MGCM-LMD model, on the other hand, predicted peak H escape flux at perihelion based on atmospheric dynamics driven by variations in EUV flux due to changing Mars-Sun distance (Chaufray et al., 2015). The model includes a “classic” dust scenario corresponding to Mars Global Surveyor (MGS) observations of dust opacity during Martian year 27 and does not consider dust storm conditions, which are prevalent during the onset of southern summer at Mars. The introduction of water vapor at high altitudes could result in an enhanced escape of water over a time scale of weeks because water vapor at high altitudes can be directly photodissociated by EUV light creating H atoms, which can then escape (Chaffin et al., 2017). SPICAM observations conducted during the 2007 global dust storm found a good correlation between aerosol vertical extension and increased water vapor content (4 to 5 times) at altitudes between 60 and 80 km between  $L_s = 268^\circ$  and  $285^\circ$  for the southern hemisphere (Fedorova et al., 2017).

During the 20 September and 21 October 2016 observations, the intensity of the Martian exospheric Lyman  $\alpha$  emission varied by less than 1%, with the corresponding H escape flux values remaining almost the same (Figure 4). This breaks the symmetry of a sinusoidal variation from seasonal changes as reported earlier in Bhattacharyya et al. (2015). From Tables 1 and 2 it is evident that the solar Lyman  $\alpha$  flux was almost a

**Figure 4.** The escape flux of H calculated from the one-component model (top) and two-component model (bottom) analysis of the HST data. Both these figures show that the peak in escape was after Mars passed the perihelion position in its orbit. Also, the H escape flux at  $L_s \sim 226^\circ$  for low solar activity was different from the H escape flux obtained at  $L_s \sim 232^\circ$  for high solar activity. The escape flux values derived at  $L_s \sim 226^\circ$  and  $L_s \sim 246^\circ$  for low solar activity are almost at the same level on account of the overlapping intensity profiles for those observations (20 September and 21 October 2016) as shown in Figure 2.

larger and more variable than the changes recorded for the solar Lyman  $\alpha$  flux at line center. The MGCM modeling study also indicated that there could be diurnal variations in hydrogen density with a peak in the dawn region during equinoxes and a peak on the nightside during solstices. Therefore, atmospheric dynamics driven by solar EUV activity could play a major role in facilitating the short-term seasonal trend in H escape found in the data.

A study on the effect of solar activity on H escape is also presented in this paper by combining all the derived H escape fluxes from all the HST observations of the Martian corona to date (Figure 4). The HST observations were conducted over different solar activity periods. Two of the observations almost overlap in solar longitudes but were conducted during different solar activity conditions. The HST observation of Mars conducted on 12 November 2014 ( $L_s \sim 232^\circ$ , Martian year 32) was during high solar activity with an  $F_{10.7} \sim 170$ , whereas the HST observation of Mars conducted on 20 September 2016 ( $L_s \sim 226.3^\circ$ , Martian year 33) was during low solar activity with an  $F_{10.7} \sim 85$ . The Martian exospheric Lyman  $\alpha$  intensity was much brighter (38%) and the corresponding H escape flux greater (101% for the one-component model and 77% for the two-component model) for the 2014 observation at high solar activity than the 2016 observation at low solar activity, even though Mars was almost at the same position in its orbit around the Sun for both the observations as shown in Figure 4. This suggests that the observed seasonal changes in the hydrogen exosphere of Mars have some correlation with solar activity with regard to long-term changes in the hydrogen exosphere. However, the short-term seasonal changes are more likely driven by lower atmospheric dynamics.

constant (changes less than 9%) between 20 September 2016 and 19 January 2017, whereas the H escape flux varied by a factor of  $\sim 2.5$  over that time period. This indicates that the seasonal variation in H escape works on a much shorter time scale than the variation of Lyman  $\alpha$  flux from the Sun. Therefore, there are other intrinsic factors at play, one of them being the presence of water vapor at high altitudes, which could shorten the time scale of seasonal changes in H escape as observed. The increased water vapor content (2–3 times) at high altitudes (50–80 km) detected by SPICAM on Mars Express (Fedorova et al., 2009; Maltagliati et al., 2013) even in the absence of a dust storm (Fedorova et al., 2017) would bypass the slow and long transport of H via  $H_2$  and support the short-term changes in the quantity of H available for escape from the exobase (Chaffin et al., 2014; Clarke et al., 2014). The viability of this process has been demonstrated in a photochemical model (Chaffin et al., 2017). Recently predicted water density profiles through photochemical modeling using data on protonated species ( $OH^+$ ,  $H_2O^+$ , and  $H_3O^+$ ) present in the atmosphere of Mars measured by the Neutral Gas and Ion Mass Spectrometer (NGIMS) on board MAVEN quote values for the mixing ratio of water vapor at 80 km to be  $\sim 0.4$  parts per billion (Fox et al., 2015), which is much lesser than measurements by MEX which go up to few tens of parts per million at those altitudes (Maltagliati et al., 2013). However, the photochemical model study suggests that the amount of water vapor that could be present at high altitudes cannot be very high due to the presence of substantial amounts of  $HCO^+$  in the same region of thermosphere as detected by NGIMS, which would otherwise be destroyed by  $H_2O$  through proton transfer reactions (Fox et al., 2015). Therefore, the amount of  $H_2O$  is bracketed by the quantity of  $H_3O^+$  and  $HCO^+$  present in the Martian thermosphere (Fox et al., 2015).

Mars Global Circulation Modeling (MGCM) suggests that the density of hydrogen at the exobase could vary up to an order of magnitude throughout a Martian year due to variations in the incident solar EUV flux from the changing Mars-Sun distance because of atmospheric dynamics (Chaufray et al., 2015). Changes in solar EUV flux are much

## 5. Summary and Discussion

HST observations of the Martian hydrogen exosphere in the FUV were conducted between September 2016 and January 2017 to document the seasonal changes in the escape of hydrogen as Mars passed perihelion and southern summer solstice. These observations were analyzed using a radiative transfer model to determine the best fit density and temperature at the exobase of Mars (200 km), which were then used to provide constraints on the escape flux of hydrogen from the exosphere of Mars. It was found that the Lyman  $\alpha$  brightness of the Martian exosphere reached its peak intensity around or after southern summer solstice rather than near perihelion. The changes in intensity were not steady and symmetric and showed some dependence with solar activity in the long run. The trends in the data also agree well with observations made by the SWIA instrument on board the MAVEN spacecraft (Halekas, 2017).

The absolute values of hydrogen escape flux reported here have significant uncertainties associated with them due to several contributing factors as discussed in Bhattacharyya et al. (2017). However, the observed trends in seasonal variation and variation with solar activity are quite significant, and the trend is independent of the uncertainties in instrumental absolute calibration. The observed long-term ( $\sim 10$  years) variations in H escape flux, as shown in Figure 4, is not inconsistent with changes in solar activity. However, for the short-term changes ( $\sim 1$  month) observed during a single Martian year as Mars moved over different solar longitudes, the changes do not seem to be directly affected by the differences in solar EUV activity recorded at Mars during that time. This implies that there are internal processes, such as upward flux of water into the middle atmosphere (Chaffin et al., 2017), that contribute to the short-term seasonal changes in the escape of hydrogen from Mars. Until the underlying drivers of the changes have been clearly understood, it will be difficult to accurately determine the total amount of water lost by Mars over its history.

## Acknowledgments

This work is based on observations with the NASA/ESA Hubble Space Telescope, obtained at the Space Telescope Science Institute (STScI), which is operated by AURA for NASA. These observations were supported by STScI grant GO-14752 to Boston University. All the HST data can be downloaded from the Space Telescope Science Institute at <http://archive.stsci.edu/hst/search.php>.
