ABSTRACT

The 2015 reactivation of the Cotopaxi volcano urges us to understand the complex eruptive dynamics of Cotopaxi for better management of a potential major crisis in the near future. Cotopaxi has commonly transitioned from andesitic eruptions of strombolian style (lava flows and scoria ballistics) or nuées ardentes (pyroclastic flows and ash falls) to highly explosive rhyolitic ignimbrites (pumiceous pyroclastic flows), which entail drastically different risks. To better interpret geophysical and geochemical signals, Cotopaxi magma storage conditions were determined via existing phase-equilibrium experiments that used starting materials chemically close to the Cotopaxi andesites and rhyolites. The results suggest that Cotopaxi's most mafic andesites (last erupted products) can be stored over a large range of depth from ~7 km to ≥ 16 km below the summit (pressure from ~200 to ≥ 400 MPa), 1000 °C, NNO +2, and contain 4.5-6.0 $\pm$ 0.7 wt% H₂O dissolved in the melt in equilibrium with ~30-40% phenocrysts of plagioclase, two pyroxenes, and Fe-Ti oxides. These mafic andesites sometimes evolve towards more silicic andesites by cooling to 950 °C. Rhyolitic magmas are stored at 200-300 MPa (i.e. ~7-11 km below the summit), 750 °C, NNO +2, and contain ~6-8 wt% H₂O dissolved in a nearly aphyric melt (less than 5% phenocrysts of plagioclase, biotite, and Fe-Ti oxides). Although the andesites produce the rhyolitic magmas by fractional crystallization, the Cotopaxi eruptive history suggests reactivation of either reservoirs at distinct times, likely reflecting flux or time fluctuations during deep magma recharge.

Keywords: Cotopaxi; andesite; rhyolite; experimental petrology; eruptive dynamics

1. Introduction

After 13 significant eruptions since 1534, a major eruption in 1877, and a VEI 1 eruption in 1949, Cotopaxi volcano started to reactivate in 2001-2002 (Kumagai et al., 2010; Molina et al., 2008). In August 2015, phreatomagmatic eruptions followed four months of precursory activity including a major seismic crisis (Gaunt et al., 2016). Although this crisis was small to moderate in intensity and ash volume erupted ($8.6 \times 10^5 \text{ m}^3$; Bernard et al., 2016), this does not preclude a major magmatic crisis in the near future. The densely populated surroundings of the volcano make the monitoring and forecasting of the volcano's activity of highest priority and urge us to understand the complex eruptive dynamics of Cotopaxi. Therefore, the present study focusses on the understanding of the magma genesis and storage conditions below Cotopaxi.

1.1. Geological setting

The Cotopaxi volcano results from the eastward subduction of the oceanic Nazca Plate beneath the continental South American Plate, with an estimated dip of 25-35 °C and a depth to the slab beneath the arc front of ~100-150 km (Taboada et al., 2000; Font et al., 2013). From north to south of the South American continent, this subduction zone defines four volcanic zones (the Northern, Central, Southern, and Austral Volcanic Zones) and generates two parallel mountain regions from east to west (the Eastern and Western Cordilleras). The Cotopaxi volcano belongs to the Eastern Cordillera of the Northern Volcanic Zone in the Ecuadorian Andes, located 60 km south of Quito and 35 km northeast of Latacunga (Fig. 1A). The volcano has a massive conical shape (22 km diameter) culminating at 5897 m high, with steep flanks capped with a glacier. The crustal thickness beneath the Cordillera of the Northern Volcanic Zone is estimated ~70 km (Feininger and Seguin, 1983; Taboada et al., 2000; Araujo, 2016), and is one of the thickest north of the Central Andes.

1.2. Cotopaxi eruptive dynamics and magma compositions

Cotopaxi has long been considered as an andesitic volcano of strombolian-type erupting scoria ballistics and lava flows associated with large lahars, based on its 1534 to present activity. However, Hall and Mothes (2008) revealed the importance of Cotopaxi rhyolitic volcanism that generated large pumiceous pyroclastic flows and ash fallouts starting 560 kyr

ago. In fact, Cotopaxi has been commonly alternating strombolian andesitic eruptions with rhyolitic ignimbrites (pyroclastic flows), without generating intermediate (dacitic) magma compositions. There is no systematic trend towards more or less evolved magma through time, although the frequency of rhyolitic eruptions is greater in the earlier Cotopaxi edification stage than in the recent period. To reconcile magma fractionation (from basaltic andesite to rhyolite) over long storage timescales (~ 74 kyr, determined by U-series data; Garrison et al., 2006) with the high frequency of the rhyolitic eruptions (separated by ~ 2 kyr), Garrison et al. (2011) proposed a long-lived rhyolitic reservoir partially tapped at repeated intervals. Because either eruptive style (strombolian or siliceous pyroclastic flows and ash falls) entails drastically different hazards and risk assessment, the prerequisite is to understand the plumbing system beneath Cotopaxi (number of reservoirs, storage depths, and volatile contents), the petrogenetic relationships between the different magmas and the mechanisms that control the eruptive dynamics.

1.3. Stratigraphy

The stratigraphy of Cotopaxi deposits has been defined by Hall and Mothes (2008) and is summarized in Fig. 1B. The eruptive deposits are divided into Cotopaxi I and II sequences. Cotopaxi I lasted from 420 to 560 kyr and is characterized by ~ 10 km³ DRE deposits of rhyolitic ignimbrites and ash falls called the Barrancas series (paleo-Cotopaxi edifice). The overlaying Chalupas Ignimbritic series (~ 100 km³ DRE), dated to 211 kyr and produced by the Chalupas caldera's paroxysmal eruption 15 km to the southeast, marks the transition to the younger Cotopaxi II sequence. This sequence is divided into the lower Cotopaxi IIA units dated from ~ 13 -20 to 4.5 kyr BP and the upper Cotopaxi IIB (to present). The Cotopaxi IIA section alternates rhyolitic ignimbrites, such as the F-series (five major eruptions of about 6 km³ DRE total volume) with andesitic scoria and lava flows. Erupted volumes slowly increase with time (total of ~ 1 -2 km³ DRE) and end with a major flank collapse event. The Cotopaxi IIA is separated from the Cotopaxi IIB section by the Colorado Canyon Ignimbrite dated to 4.5 kyr BP (~ 1 km³ DRE). The Cotopaxi IIB sequence comprises a series of andesitic scoria falls and lava flows (~ 7 km³ DRE), with minor rhyolitic episodes occurring ~ 2.2 kyr BP called the Peñas Blancas rhyolites (~ 0.6 km³ DRE). From the stratigraphy, it thus appears that Cotopaxi was more rhyolitic and explosive at the beginning of its edification, turning into more mafic and effusive with time (even if the recent activity still shows sparse Plinian episodes of rhyolitic magmas). The historical activity, mainly reported in chronicles and

reports and summarized in Pistolesi et al. (2011), consists of VEI 2 to 4 eruptions of scoria-rich flows and falls and lava flows, such as those of 1534, 1742, 1768, 1877 and 1880 (all representing $\sim 1\text{-}3 \text{ km}^3$ DRE; Hall and Mothes, 2008). The Quilotoa volcano emitted a very distinctive dacitic biotite-bearing ash fall deposit dated to 810 yr BP (Hall and Mothes, 2008) that has been used as a date marker for the younger Cotopaxi deposits.

1.4. Objectives and approach

Below, magma storage conditions for Cotopaxi will be constrained by using phase-equilibrium experiments on magma compositions different from but close to those present on the volcano. Instead of acquiring a full set of experimental data over a broad field of conditions for the various Cotopaxi magmas (an approach that necessarily requires time), we make use of already existing experimental studies. The whole approach can thus be viewed as a guided interpolation and extrapolation of experimental data. The main motivation is to test if, with this approach, results can be made available rapidly to help interpreting daily acquisition of geophysical and geochemical signals. Phase-equilibrium data for specific magma compositions emitted at a given volcano might not directly apply elsewhere and, so, we are ready to accept larger uncertainties in determined storage conditions than, for example, with the direct experimental approach. However, this choice is made for the benefit of a faster response, an important issue in the case of volcanic unrest.

2. Sample geochemistry and petrology

The whole-rock major-elements geochemistry and petrology of the Cotopaxi samples come from Garrison et al. (2011), with some additional analyses for the historical eruptions from Pistolesi et al. (2011) (both determined by inductively coupled plasma-mass spectroscopy). In Garrison et al. (2011), minerals and matrix glasses were analyzed by electron microprobe. Here, new mineral and glass analyses are provided, as well as glass H_2O contents for one sample from the andesitic 1877 eruption and one pumice from the Peñas Blancas rhyolitic eruption (SX-five electron microprobe; ISTO, Orléans; Supplementary Material SM1). The compilation of the whole-rock major-elements data confirms two distinct magma compositions: andesite ($\sim 56\text{-}62 \text{ wt\% SiO}_2$) and rhyolite ($\sim 70\text{-}76 \text{ wt\% SiO}_2$), with a chemical gap between 62 and 70 wt% SiO_2 (Fig. 2).

2.1. Andesites

2.1.1. Whole-rock composition

The andesite group shows a significant scatter from 56 to 64 wt% SiO₂ and from ~2 to nearly 5 wt% MgO (Fig. 2). Within this group, there is an interesting difference in eruptive style between, on the one hand, the SiO₂-poorer and MgO-rich magmas that erupt as strombolian-type and lava flows and, on the other hand, the SiO₂-richer and MgO-poorer magmas that erupt explosively as pumiceous pyroclastic flows and ash falls. Therefore, two contiguous groups have been defined: one with MgO < 2.5 wt% and SiO₂ > 60 wt%, hereafter referred as Si-andesites (e.g. the Peñas Blancas andesite eruption) and the other with MgO of 3-5 wt% and SiO₂ < 60 wt%, hereafter referred as Mg-andesites (e.g. the 1877 eruption). Interestingly, both magma compositions (and hence both eruptive styles) are present within a given edification sequence (Cotopaxi IIA or IIB), even among recent eruptions (the post 1130 AD layers mainly contain Si-andesite pumices whereas the other eruptions are mostly Mg-andesite scoria; Pistolesi et al., 2011). The most recent Cotopaxi magmas are the most mafic (rich in MgO and poor in SiO₂).

2.1.2. Phenocrysts

All Cotopaxi andesites, whether pumice or lava/scoria, contain 23 to 48 modal% phenocrysts (Garrison et al., 2011). The phenocrysts are mainly plagioclase (~80% recalculated on a bubble-free basis), orthopyroxene, clinopyroxene, and minor Fe-Ti oxides (magnetite ± ilmenite) (SM2).

The plagioclases in both Mg- and Si-andesites show compositions from 45 to 95 mol% anorthite (An₄₅₋₉₅), with a main frequency mode at ~An₅₅₋₆₅ (Fig. 3A). Garrison et al. (2011) noted little compositional variation between cores and rims. Our new plagioclase analytical profiles of 1877 Mg-andesite crystals show complex zoning, commonly spanning a total compositional range of An₄₅₋₇₀, with rim compositions around An₅₅₋₆₀ (except for one crystal with a An₇₆₋₈₇ profile either inherited from more mafic compositions or reheated; Fig. 4). Phenocryst rim compositions have more chances to represent chemical equilibrium with the melt just prior to eruption, following the ‘local equilibrium’ concept of Pichavant et al. (2007). No analytical profiles were performed on Si-andesite plagioclases, but limited (n = 13) punctual analyses show that the most sodic compositions that could represent plagioclase rims are An₅₅₋₆₀ (Fig. 3A).

The orthopyroxenes in the Si-andesites show a narrow compositional range of 66-72 mol% enstatite (En_{66-72} ; $n = 9$), with a main mode at En_{68-72} . The Mg-andesites span a large compositional range from En_{60} to En_{78} , with a main frequency mode at En_{68-72} similar to that in Si-andesites (Fig. 3B). Punctual rim analyses and profiles show rim compositions of En_{68-70} in Si-andesites and En_{72-74} in Mg-andesites. For both andesite groups, clinopyroxenes have between 38 to 45 mol% wollastonite (Wo_{38-45}), with a main frequency mode at Wo_{41-43} (Fig. 3B). In Mg-andesites, clinopyroxene rim compositions are $\text{Wo}_{41-42}\text{En}_{41-42}$ (e.g. SM1 for the 1877 AD eruption) and, for Si-andesites, $\text{Wo}_{43-44}\text{En}_{40-45}$. Both pyroxenes show similar Mg-numbers ($\text{Mg\#} = \text{molar Mg}/(\text{Fe}+\text{Mg})$) of $0.74_{\pm 0.02}$ and $0.72_{\pm 0.03}$ for the Mg- and Si-andesites, respectively.

Magnetites in Si-andesites show restricted compositions from 72 to 75 mol% magnetite (Mt_{72-75}), with a main mode at Mt_{73-74} . In Mg-andesites, magnetites show a slightly wider range (Mt_{70-77}) and a bimodal distribution, with the main mode at Mt_{75-76} and a secondary mode at Mt_{72-74} that overlaps with Si-andesites (Fig. 3C). Traces of ilmenite occur in both andesites.

2.1.3. Composition and H_2O content of the glass inclusions and matrix glasses

Glass inclusions are mostly hosted in pyroxenes, with typical size of 10-30 μm in diameter, and they contain rare bubbles and small amounts of iron-rich daughter minerals (i.e. Fe-Ti or Fe-Mg minerals; SM2D). The matrix glasses and glass inclusions in the Mg-andesites show extremely variable compositions from 60 to 75 wt% SiO_2 (Fig. 5), essentially filling the bulk-rock compositional gap (Fig. 2). A group of matrix glasses in a Mg-andesite lava (CTX-75 identified as 'lava' in Garrison et al., 2011) has extremely SiO_2 -rich compositions (78-82 wt% SiO_2 ; from the 'Old andesite MG' group in Fig. 5). Such silica-rich glasses may result from cooling-induced extensive microlite crystallization during lava flow emplacement (i.e. they differ from the matrix glasses analyzed in microlite-poor pumice or scoria). However, even if values above 75 wt% SiO_2 are exceptional, glasses still cover a wide range of composition (62-72 wt% SiO_2). The matrix glasses for one of the 1877 samples range between 62 and 64 wt% SiO_2 and are thus more mafic than the glass inclusions (63-70 wt% SiO_2 ; SM1). This, together with rounded phenocrysts and skeletal $\sim\text{An}_{60}$ microlites (SM2D; SM1), suggests a mixing event involving a more mafic and hot liquid just before eruption. If the time lapse between recharge and eruption is short, the mixing may only occur between both matrixes (resident andesite and newly injected liquid), without significantly incurring modifications of the phenocryst rims, as proposed by Martel et al. (2006). Consequently, the residual glasses

analyzed in the erupted products are not in chemical equilibrium with the phenocryst rims, and may be more mafic than the glass inclusions. The 64-67 SiO₂ wt% matrix glasses in ashes identified as juvenile material from the 2015 phreatomagmatic eruption (Gaunt et al., 2016) show trends in some oxides (e.g., Al₂O₃, CaO, FeO) that deviate from a crystal fractionation trend (Fig. 5), possibly reflecting some mixing effects comparable to those in 1877.

The glasses have been analyzed for their volatile content (assumed to be H₂O), using the electron microprobe and different standard glasses of dacitic and rhyolitic compositions for which the H₂O content is well-known (data and methods in SM1). The glass inclusions hosted in pyroxenes from the 1877 Mg-andesite show H₂O contents from 0.8 to 3.5 $\pm$ 0.7 wt%, without significant differences whether hosted in orthopyroxene (En₆₈ to 70) or clinopyroxene (Wo₃₈ to 44; Fig. 6). Matrix glasses in the 1877 Mg-andesite have H₂O contents $\leq$ 1.0 wt% (SM1), but the reheated nature of this sample makes them suspicious.

2.2. Rhyolites

The whole-rock geochemistry of the rhyolites all comes from Garrison et al. (2011). Fig. 2 shows that Cotopaxi IIB Peñas Blancas rhyolites have compositions similar to Cotopaxi IIA F-series. All rhyolites contain 2-4 % phenocrysts of plagioclase, biotite, and minor amounts of quartz, magnetite, ilmenite, apatite, allanite, and zircon (SM2A). Amphibole is reported in the last and least-evolved F-series deposits (F4, sample CTX19 in Garrison et al., 2011). It is lacking in the Peñas Blancas rhyolites and the Barrancas series of Cotopaxi_I's early edification stage, although some younger units of this latter series show traces of amphibole, K-feldspar, and pyroxenes (Hall and Mothes, 2008). Mineral chemistry data are available for the F-series (Garrison et al., 2011), with some additional data for the Peñas Blancas rhyolites (SM1). The plagioclase composition ranges from An₂₇ to An₅₂, showing a main frequency mode at An₃₀₋₃₅ (Fig. 3A) that corresponds to rim compositions (Fig. 4). The magnetite compositional range is narrow, from Mt₈₃ to Mt₈₆, showing a main frequency mode at Mt₈₄₋₈₅ (Fig. 3C). Ilmenites have 77 $\pm$ 4 mol% ilmenite (Ilm_{77 $\pm$ 4}). Biotite compositions show 2.1 to 2.4 mol% Al and Mg# from 0.5 to 0.7 (Bt_{0.5-0.7}). In the F-series, Wo₄₁₋₄₂ clinopyroxenes (Fig. 3B) and amphiboles containing 11 wt% Al₂O₃ (Am₁₁), ~1.6-1.8 pfu Al^{IV}, 0.4-0.5 pfu cations in the alkali (A) site, and Mg# ~0.66 $\pm$ 0.02 (Fig. 7) have been found. The matrix glasses have SiO₂ contents from 75 to 81 wt% (Fig. 5; n.b., the scatter in alkali contents likely reflects inappropriate analytical conditions). Unfortunately, we did not find any glass inclusion in the phenocrysts.

The ignimbrites from Chalupas Caldera (not belonging to Cotopaxi edifice) and Colorado Canyon Series (unclear origin) show comparable whole-rock geochemistry (Fig. 2). Both ignimbrites have K₂O contents higher by nearly 2 wt% compared to the Cotopaxi rhyolites (as well as ~1 wt% less Na₂O and slightly higher TiO₂ contents). The Chalupas Caldera ignimbrite and most of the Colorado Canyon ignimbrite show a phenocryst assemblage similar to that of the Cotopaxi rhyolites, although lacking amphibole (except for pristine reaction-free amphibole reported in the least evolved Colorado Canyon ignimbrite; Garrison et al., 2011).

2.3. Summary

The Cotopaxi Mg-andesites are characterized by 23 to 42 % phenocrysts made of An₅₅₋₆₀-rimmed plagioclase, En₇₂₋₇₄-rimmed orthopyroxene, Wo₄₁₋₄₂En₄₁₋₄₂ rimmed clinopyroxene (both pyroxenes with Mg# ~0.74_{±0.02}), and Mt₇₅₋₇₆, in a 62-72 wt% SiO₂ matrix glass. Glass inclusions contain up to 3.5_{±0.7} wt% H₂O.

The Si-andesites are characterized by 23 to 42 % of the same phenocrysts, with slightly different compositions: An₅₅₋₆₀ (plagioclase rims), En₆₈₋₇₀, Wo₄₂₋₄₃ (both pyroxenes with Mg# ~0.72_{±0.03}), Mt₇₃₋₇₄. The matrix glass has ~66 wt% SiO₂ but only two analyzes are available. There are no data for glass inclusions and volatile contents.

The rhyolites are characterized by 2-4 % phenocrysts of An₃₀₋₃₅, biotite with 2.1-2.4 wt% Al₂O₃ and Mg#_{0.5-0.7}, Mt₈₄₋₈₅, and Ilm_{77±4}, in a 75-81 wt% SiO₂ matrix glass. Wo₄₁₋₄₂ clinopyroxenes and amphibole (11 wt% Al₂O₃ and Mg# 0.66_{±0.02}) have been reported. There is no data for glass inclusions and volatile contents.

3. Crystallization conditions determined from the natural samples

3.1. Andesites

The composition of coexisting orthopyroxene and clinopyroxene can be used to infer crystallization temperatures using two-pyroxene thermobarometry. Using the formulation of Putirka (2008), the pyroxene pairs that passed the test of equilibrium crystallization (based on the Fe-Mg exchange coefficient) suggest temperatures (*T*) ~980 °C and pressures (*P*) ~440 MPa for the Si-andesite (one single pair) and ~990-1040 °C and 565-965 MPa for the Mg-andesites (SM3A). Using a density of ~2700 kg/m³ for andesitic rocks, this gives depths of

~16 and 21-36 km below the summit, respectively. Nevertheless, these calculations must be taken with caution, since results on 200-MPa andesitic experimental samples show systematic overestimations of temperature by ~100 °C and of pressure by > 100 MPa (SM3A).

The composition of the liquid in equilibrium with plagioclase may be used to estimate T and H_2O content using plagioclase-liquid thermohygrometers. The main difficulty with the Cotopaxi andesites is the compositional scatter of the glasses, either matrix glasses or glass inclusions (Fig. 5). In addition, the glass inclusions are not trapped in plagioclase but in pyroxenes, which does not guarantee plagioclase-liquid equilibrium. Both andesites have plagioclase rims of ~An₅₅₋₆₀ but, depending on the melt composition and T considered, H_2O contents calculated using the formulation of Water and Lange (2015) vary from 3.3 to 4.9 $_{\pm 0.4}$ wt% H_2O at 950 °C and from 1.2 to 2.7 $_{\pm 0.4}$ wt% H_2O at 1100 °C. In these calculations performed at P between 200 and 600 MPa, the highest bounds correspond to the most silicic (64 wt% SiO_2) and the lowest bounds to the most mafic (61 wt% SiO_2) matrix glass compositions (SM3B). Using the glass inclusions, H_2O contents vary from 3.9 to 4.7 $_{\pm 0.4}$ wt% H_2O at 950 °C and from 1.9 to 2.6 $_{\pm 0.4}$ wt% H_2O at 1100 °C for SiO_2 contents between 63 and 75 wt% and P between 200 and 600 MPa (SM3B). The maximum H_2O contents of 3.5 $_{\pm 0.7}$ wt% measured in pyroxene-hosted glass inclusions are consistent with crystallization in a 950-1100 °C T range (SM3B).

To summarize, the crystallization conditions retrieved from the andesitic samples suggest T ~950-1100 °C, melt H_2O content from ~1.2-2.7 wt% at 1100 °C to ~3.3-4.9 wt% at 950 °C, and poor constraints on pressure. Lack of ilmenite analyses prevented the retrieval of oxygen fugacity (f_{O_2}).

3.2. Rhyolites

Magnetites and ilmenites that passed the test of chemical equilibrium (Bacon and Hirschman, 1988) suggest T from 728 to 774 $_{\pm 50}$ °C and f_{O_2} close to 2.0 $_{\pm 0.1}$ log units above the Ni-NiO oxygen buffer (ΔNNO +2.0 $_{\pm 0.1}$) after the calculation of Sauerzapf et al. (2008) (SM3C). The high Mg# (~0.5-0.7) in biotite and in amphibole (~0.7; Fig. 7B) are both consistent with a f_{O_2} close to NNO +1.5.

Fig. 7A shows that the compositions of amphiboles analyzed in one of the F-series rhyolites (Garrison et al., 2011) are not compatible with crystallization from a rhyolitic liquid at either 100 or 400 MPa (i.e. 4 or 15 km below the summit). The Al/Si ratio of these amphiboles is about 0.32, which is similar to those of the dacitic interstitial glasses of the

andesites (~64 wt% SiO₂ and ~17 wt% Al₂O₃, SM1; bulk-rocks of rhyolites, Si-andesites, and Mg-andesites show ratios of about 0.24, 0.36, and 0.39, respectively). Therefore, these amphiboles likely crystallized from a dacitic liquid and were incorporated into the rhyolitic magma. Since they are only reported in the least evolved rhyolitic magmas (i.e., ~72 wt% SiO₂), it seems to be a peculiarity of low-silica rhyolites that do not represent the majority of the erupted rhyolites at Cotopaxi. Therefore, we will no longer consider amphibole as belonging to the rhyolitic phase assemblage. Similarly, the rare clinopyroxenes found in the F-series rhyolites have the same composition than those of andesites (Fig. 3B), likely reflecting inherited crystals.

The melt H₂O contents, calculated from the plagioclase-melt geohygrometer of Water and Lange (2015) for a 78_{±2} wt% SiO₂ matrix glass in equilibrium with An₃₀₋₃₇, range from 3.8-4.3_{±0.4} wt% at 900 °C, 6.1-6.6_{±0.4} wt% at 800 °C to 9.3-9.6_{±0.4} wt% at 700 °C (*P* from 200 to 600 MPa; SM3B). Use of the RHYO-MELTS software is not appropriate for the Cotopaxi rhyolites since alkali feldspar is virtually absent and biotite is present.

To summarize, the crystallization conditions retrieved from the rhyolite phase compositions suggest *T* of 728-774_{±50} °C and *f*O₂ close to NNO +2. For *T* between 700 and 800 °C, calculated melt H₂O contents vary from 6 to 9 wt%. *P* remains unconstrained.

4. Phase equilibria

To refine magma crystallization conditions constrained from the natural samples, phase-equilibrium experiments performed on natural magmas different but very close to the Cotopaxi Mg-andesite, Si-andesite, and rhyolite will be analyzed below. The selection of candidate experimental studies was guided by two main criteria. (i) The first is the composition used as starting material which must approach Cotopaxi magmas since a 1-2 wt% difference in major elements such as SiO₂, Al₂O₃, CaO, alkalis (Na₂O and K₂O), FeO_t or MgO is enough to significantly change the phase assemblage and crystallization sequence (see for instance Cadoux et al., 2014). (ii) The second is the *P-T-f*O₂-*f*H₂O conditions covered in candidate studies which must encompass the range expected for magma storage at Cotopaxi. Compositions of minerals and melts must also have been determined in candidate studies since their dependence with experimental variables provides the most precise constraints on crystallization conditions (e.g. Rutherford et al., 1985). For this reason, only redox-controlled studies were considered because *f*O₂ directly affects experimental compositions (e.g. Martel et al., 1999).

In the selected experimental studies, the water concentration is expressed in various ways. To allow comparison between them all, the initial mole fraction of H₂O ($X_{\text{H}_2\text{Oin}}$) will be used below instead of the water activity ($a_{\text{H}_2\text{O}}$) or the melt water content (wt% H₂O). This is because calculation of $a_{\text{H}_2\text{O}}$ or wt% H₂O depends on the particular H₂O solubility model chosen. $X_{\text{H}_2\text{Oin}}$ will eventually be converted into melt H₂O contents, (i) for rhyolites, by using the H₂O solubility model of Newman and Lowenstern (2002), with $P \sim P_{\text{H}_2\text{O}}$ (approximated by $X_{\text{H}_2\text{Oin}} * P_{\text{total}}$) and (ii) for Mg-andesites, by measuring H₂O contents in the experimental charges following the by-difference method of Devine et al. (1995). This last method has the benefit of being that used to measure the H₂O contents in glass inclusions and it avoids errors when applying solubility models to Mg-andesite melts for which calibration data are lacking.

4.1. Mg-andesites

4.1.1. Selection of experimental studies

Two experimental studies have been selected on the basis of the criteria above, one performed on the Mg-rich andesite of the August 2006 Tungurahua eruption, Ecuador (**TUN**; Andújar et al., 2017) and the other on the andesite of the Unzen 1991-95 eruption, Japan (**UNZ**; Botcharnikov et al., 2008). Both andesites show MgO, SiO₂, Al₂O₃, CaO, FeO, and K₂O contents consistent with Cotopaxi Mg-andesites (Fig. 2). Yet, both andesites comparatively lack ~0.5 wt% Na₂O, but still compare in terms of total alkali (Na₂O+K₂O) content (Fig. 2). The phase equilibria have been determined at NNO-0.5 for **UNZ** and NNO+1 and NNO+2 for **TUN**. Using experimental phase relationships and compositions from these studies, we seek for P - T - f_{O_2} - $f_{\text{H}_2\text{O}}$ conditions that simultaneously yield 23-48 wt% crystals of An₅₅₋₆₀, Wo₄₀₋₄₁, En₇₂₋₇₄ and Mt₇₅₋₇₆ in a 62-72 wt% SiO₂ liquid containing up to 3.5_{±1} wt% H₂O (see above). Results are discussed for different pressures/depths below.

4.1.2. Pressure of 100 MPa / 4 km depth

The H₂O-saturated ($X_{\text{H}_2\text{Oin}} = 1$) **TUN** experiments performed at 975 to 1000 °C, NNO +1, or 1000 °C, NNO +2, both crystallized olivine, a phase that does not belong to the Cotopaxi phase assemblage. Clinopyroxenes in H₂O-undersaturated olivine-free charges have Wo contents (<Wo₄₀) too low to match those of Cotopaxi andesites. Therefore, the available constraints rule out a P of 100 MPa for Mg-andesite crystallization at Cotopaxi.

4.1.3. Pressure of 200 MPa / 7 km depth

Both **UNZ** and **TUN** phase diagrams have a T - $X_{\text{H}_2\text{Oin}}$ field at $0 < \Delta\text{NNO} < +1$ where the natural Cotopaxi Mg andesite assemblage is reproduced. For conditions within this field, however, no clinopyroxene has $\text{Wo} > 40$, no orthopyroxene has $\text{En} > 65$ and no magnetite has $\text{Mt} > 60$ (SM4A). At NNO +2, the **TUN** charge at 975 °C and $X_{\text{H}_2\text{Oin}} \sim 0.7$ almost reproduces the phenocryst proportion (32% crystals), assemblage and compositions at Cotopaxi (Fig. 8A). One minor discrepancy concerns clinopyroxene, slightly more En-rich in the experimental charge (En_{44-48}) than in Cotopaxi products (En_{41-42} ; Fig. 8A).

4.1.4. Pressure of 400 MPa / 16 km depth

At NNO +1, the **TUN** experiment at 1000 °C and $X_{\text{H}_2\text{Oin}} \sim 0.7$ (29 wt% crystals, SM4B) is very close to reproduce the Cotopaxi phase assemblage and compositions. Magnetites were too small to be analyzed in that charge but, based on results at 200 MPa for the same $f\text{O}_2$ (SM4A), their composition ($\text{Mt} < 60$) would imply conditions that are too reduced for Cotopaxi. Yet, experiments at NNO +2, $T \sim 1000$ °C and $X_{\text{H}_2\text{Oin}}$ of 0.6-0.7 yield the appropriate phase assemblage (30 to ~50 % crystals, Fig. 8B) and the Cotopaxi Mg-andesites phenocryst compositions are nearly reproduced. Clinopyroxene in particular has En (En_{42-43}) in closer agreement with the natural compositions than those crystallized at 200 MPa.

4.2. Si-andesites

4.2.1. Selection of the experimental studies

The selected phase-equilibrium studies include those performed on the ~1350 AD P1 Plinian eruption of Montagne Pelée, Martinique (**PEL**; Martel et al., 1999), on the 55-65 ka Upper Scoria Plinian eruption of Santorini, Greece (**SAN**; Andújar et al., 2016) and on the 28 Ma Huerto lavas emplaced just after the Fish Canyon tuff, Colorado (**HUE**; Parat et al., 2008). Whereas **PEL** is quite close to Cotopaxi Si-andesites (but see below), **HUE** and **SAN** are both comparatively depleted in Al_2O_3 (by 1 and ~2 wt% respectively) and **SAN** comparatively enriched in FeO_t (by ~3-4 wt%, leading to a significantly lower Mg#) (Fig. 2). Using these studies, we seek for conditions that simultaneously yield 23-48 % crystals of An_{55-60} , Wo_{42-43} , En_{68-70} , Mt_{73-74} , coexisting with a residual liquid with ~66 wt% SiO_2 .

4.2.2. Pressure of 100 MPa / 4 km depth

No **PEL** and **HUE** experiments are available at 100 MPa but the phase relationships for **SAN** (975 to 1000 °C, NNO ~+1.5, $X_{\text{H}_2\text{Oin}}$ from 0.3 to 1; SM5A) provide several arguments to

dismiss 100 MPa as a possible crystallization pressure for Cotopaxi Si-andesites. (i) In the 975-1000 °C temperature range, crystallization of plagioclase $<An_{60}$ requires an experimental crystallinity $> 50\%$ whereas $< 50\%$ is required from natural products. (ii) Experimental clinopyroxene is too low in Wo content ($\sim Wo_{30-35}$) compared to natural phenocrysts (Wo_{42-43}). (iii) Values of $X_{H_2Oin} < 0.6$ correspond to H_2O contents lower than the maximum measured in glass inclusions (up to $3.5_{\pm 0.7}$ wt%; note that 3.5 wt% is the calculated H_2O solubility at 100 MPa, Newman and Lowenstern, 2002). Nevertheless, the specificities of the **SAN** composition (more FeO-rich and Al_2O_3 -poor than Cotopaxi Si-andesites) need consideration. For similar experimental conditions (200 MPa, 950 °C, $X_{H_2Oin} = 0.73$, $+1.5 < \Delta NNO < +2.5$), the **SAN** and **PEL** results show systematic differences. In the **SAN** charges, the crystallinity, Wo in clinopyroxene and En in orthopyroxene are higher by 10 wt%, 15 mol% and 4 mol% respectively than in the **PEL** charges, and the An in plagioclase is lower by 11 mol% (SM5B). Thus, correcting the 100 MPa **SAN** results leads to crystallinity and plagioclase An content both being closer to Cotopaxi Si-andesites. However, the discrepancy persists (it is in fact worsened) for the clinopyroxene Wo content. Therefore, we conclude that 100 MPa is not a possible crystallization pressure for Cotopaxi Si-andesites.

4.2.3. Pressure of 200 MPa / 7 km depth

The **PEL** phase equilibria reproduce the Cotopaxi phase assemblage for T from 850 to 950 °C, $X_{H_2Oin} < 0.9$ and for the two f_{O_2} investigated, although the stability field for clinopyroxene is poorly-constrained (SM5B). **PEL** crystallinities and compositions of plagioclase and glass compare well with Cotopaxi samples. Plagioclases (An_{55-60}) are reproduced below 925 °C - $X_{H_2Oin} \sim 0.7$ and at 875 °C - $X_{H_2Oin} \sim 0.9$. For these conditions, the crystallinity is about 40-48 % and the residual glass has 70-73 wt% SiO_2 , both in the upper limits of their respective ranges in Cotopaxi products. In comparison, orthopyroxene and magnetite compositions differ between experimental and natural samples. For instance, for $+2 < \Delta NNO < +3$, the natural En_{70} orthopyroxenes are well reproduced but experimental magnetites are always $> Mt_{85}$, i.e., too high for Cotopaxi Si-andesites (Mt_{74-76}). Lowering the f_{O_2} to $0 < \Delta NNO < +1$ generates Mt_{74-76} magnetites but orthopyroxenes (always $< En_{68}$) become too low in En for Cotopaxi (En_{70-72}). This mismatch between experimental and natural phase compositions is, firstly, the consequence of the f_{O_2} range in the **PEL** experiments, slightly inappropriate for Cotopaxi. It is most likely that a f_{O_2} in between the two domains investigated ($+2 < \Delta NNO < +3$ and $0 < \Delta NNO < +1$) in **PEL** experiments would yield pyroxene and magnetite compositions in

better agreement with natural products. Secondly, it is important to stress that **PEL** has a slightly lower Mg# (0.26-0.27) than Cotopaxi silicic andesites (e.g., the Peñas Blancas compositions, Mg# = 0.31-0.32; Fig. 2) and, so, for a given f_{O_2} , the **PEL** experiments underestimate the En content of orthopyroxenes in Cotopaxi magmas. Finally, the rarity of clinopyroxene in the **PEL** experiments contrasts with its systematic presence in Cotopaxi Si-andesites. This inconsistency, which accentuates with pressure since clinopyroxene is absent in **PEL** experiments at 300 and 400 MPa, is most likely of compositional origin. The **PEL** starting composition is significantly less alkali-rich than the Cotopaxi Si-andesites (Fig. 2), being more calcic than calc-alkaline. In such compositions, crystallization of An-rich plagioclase over clinopyroxene is favoured. Plagioclase is more An-rich, and so, for conditions being equal, the **PEL** experiments overestimate the An contents in Cotopaxi magmas. Therefore, if f_{O_2} is adjusted appropriately and the differences between the respective magma compositions considered, the discrepancies between **PEL** results and natural Si-andesite products can be rationalized. We conclude that 200 MPa is a possible crystallization pressure for the Cotopaxi Si-andesites.

4.2.4. Pressure of 300 MPa / 11 km depth

Two charges ($X_{H_2O_{in}} = 0.9$ and 1) are available at 925 °C, NNO +1 for the **PEL** starting material. The $X_{H_2O_{in}} = 1$ (H₂O-saturated) charge has a crystallinity of 20 % and the $X_{H_2O_{in}} = 0.9$ of 40 %. In natural products, 40 % is a maximum crystallinity and, so, $X_{H_2O_{in}} = 0.9$ is a minimum in the 300 MPa experiments. This corresponds to a H₂O concentration of ~7 wt%, a minimum which is about twice higher than the maximum ($3.5_{\pm 0.7}$ wt% H₂O) measured in the glass inclusions. Therefore, 300 MPa cannot be taken as the crystallization pressure for the Cotopaxi Si-andesite if temperature is fixed at 925 °C. Yet, increasing temperature to ~950 °C would permit 25-45 % crystallinities at lower H₂O contents.

4.2.5. Pressure of 400 MPa / 16 km depth

One set of charges is available for **PEL** at 930 °C, NNO +1 for $X_{H_2O_{in}}$ between 1 and 0.7. Amphibole crystallizes alone on the liquidus for $X_{H_2O_{in}} = 1$. For lower $X_{H_2O_{in}}$, amphibole is replaced by a plagioclase and orthopyroxene assemblage. More data are available on the **HUE** and **SAN** compositions. The phase diagrams, compiled in Fig. 9 for **HUE** (NNO) and **SAN** (NNO +1.5) as well as for **PEL** (NNO +1), define a broad domain ($X_{H_2O_{in}} < 0.6-0.7$ at ~950 °C) where the Si-andesite phenocryst assemblage is reproduced. However, as for the 200 MPa **PEL** experiments, mismatch between experimental and natural phase compositions is

observed. Orthopyroxenes in the domain above are all $< \text{En}_{64}$ and none reaches the required En_{68-70} range. In the same way, none of the magnetites outside the stability field of amphibole and within the stability field of plagioclase have the required Mt_{74-76} composition (all are $< \text{Mt}_{70}$). None of the **HUE** or **SAN** plagioclases outside the stability field of amphibole satisfy An_{55-60} (all are $< \text{An}_{51}$). Yet, the experimental En and Mt are too low to be applied directly to Si-andesite compositions because (1) they come from slightly too reduced experiments and (2) both the **SAN** and **HUE** starting compositions have lower Mg# (respectively 0.22 and 0.24) than Cotopaxi Si-andesites ($\text{Mg\#} = 0.31-0.32$, down to 0.26 for the most SiO_2 -rich products; Fig. 2). Similarly, experimental An contents (mainly **SAN** samples) must be corrected upwards to account for the Al_2O_3 -poor character of this particular starting composition. Although the corrections to be applied are difficult to evaluate rigorously, they are also all of limited importance (< 10 mol% for Mt, En and An). The important point is that they all strengthen the case for the ~ 400 MPa, $T \sim 950$ °C, $\sim \text{NNO} + 2$, and $X_{\text{H}_2\text{O}_{\text{in}}} \sim 0.5-0.7$ as a possible crystallization domain for the Cotopaxi Si-andesites.

4.3. Rhyolites

4.3.1. Selection of the experimental studies

The selected phase-equilibrium studies include those performed on the 2008 Plinian eruption of Chañten, Chile (**CHAI**; Castro and Dingwell, 2009), on a rhyolite (**WL17**; Waters and Lange, 2017), on the ~ 3.6 ka Minoan Plinian eruption of Santorini, Greece (**MIN**; Cadoux et al., 2014), on the Australian Wangrah granite (**AB412**; Klimm et al., 2003) and on the Brazilian Jamon granite (**JAM**; Dall'agnol et al., 1999). Fig. 2 shows that the **CHAI** composition (75 wt% SiO_2) is close to the most evolved Cotopaxi rhyolites, whereas **WL17**, **MIN**, **AB412**, and **JAM** (72-73 wt% SiO_2) approach the least evolved samples. In comparison with Cotopaxi, **MIN** is richer in FeO_t (by 1 wt%); the two granites (**AB412** and **JAM**) are poorer in Al_2O_3 (by 2 wt%) and richer in FeO_t (by 2 wt%).

Using experimental phase relations and compositions from those studies, we aim at defining conditions that simultaneously yield crystallization of ≤ 5 % crystals of plagioclase (An_{30-35}), biotite (with Mg# of 0.5-0.7, $\text{Bt}_{0.5-0.7}$), Mt_{84} , Ilm_{77} , and quartz in a residual liquid with 76-78 wt% SiO_2 . Amphibole is not part of the stable phase assemblage in Cotopaxi rhyolites.

4.3.2. Pressure of 200 MPa and below / ≥ 7 km depth

The **CHAI** experiments were performed at P from 50 to 200 MPa, T from 750 to 950 °C and a f_{O_2} of NNO +1. Only plagioclases and a few orthopyroxenes from run products have been analyzed. The **WL17** experiments were performed between 80 and 185 MPa, at 785 to 850 °C and a f_{O_2} close to the NNO buffer. H_2O -saturated conditions ($X_{H_2Oin} = 1$) were imposed in both studies. Experimental results show that, below 175-200 MPa (depending on the rhyolite starting composition), orthopyroxene is present as a stable phase in a wide temperature range (750-850 °C). Biotite, to be stable, requires temperatures $< \sim 775$ °C (Fig. 10). Consequently, 175-200 MPa (i.e. below ~ 7 km below the summit) is too low a pressure for the crystallization of Cotopaxi rhyolites which lack orthopyroxene phenocrysts. The rhyolitic ($An_{30-35}+Bt+Mt$) natural phase assemblage is reproduced at ~ 750 °C and ~ 200 MPa, i.e., near the liquidus (Fig. 10), consistent with the low crystallinities (< 5 wt%) required. Quartz crystallizes at a lower pressure in both the **CHAI** and **WL17** experiments (Fig. 10) and this casts doubt on the significance of quartz phenocrysts in the Cotopaxi rhyolites. Note that **MIN** and **AB412** (both with significant compositional differences with Cotopaxi rhyolites) crystallize amphibole at $T \geq 700$ °C under H_2O -saturated conditions (SM6A).

Because the **CHAI** and **WL17** runs were all H_2O -saturated, the influence of the water concentration is evaluated from the **AB412** and **MIN** results. The compiled phase diagram at 700-900 °C and $0 < \Delta NNO < +1$ (SM6A) shows that, under H_2O -undersaturated conditions, it is virtually impossible to have plagioclase and biotite crystallizing in low ($< 5\%$) amounts without orthopyroxene (and also amphibole depending on the starting composition) being also present. Although obtained on rhyolite compositions different from Cotopaxi, these results tend to restrict Cotopaxi rhyolite crystallization to conditions very close to H_2O -saturation.

4.3.3. Pressure of 300 MPa / 11 km depth

The phase diagram for the **JAM** composition at 700 to 900 °C and NNO +2.5 shows that, to achieve low crystallinities ($< \sim 5\%$) without amphibole being stable, near-liquidus H_2O -rich ($X_{H_2Oin} > 0.9$) conditions and low temperatures ($T \sim 700$ °C) are necessary (SM6B). In this very restricted domain of the phase diagram, saturation curves for plagioclase, quartz, biotite, K-feldspar and titanite all converge. The phenocryst assemblage of Cotopaxi rhyolites includes neither K-feldspar, titanite nor amphibole, which suggests that crystallization in this domain is inappropriate. In addition, the temperature required (~ 700 °C) is lower than the range inferred from Fe-Ti oxides (728-774°C). We conclude that 300 MPa represents an upper limit for the crystallization of Cotopaxi rhyolites.

4.3.4. Pressure of 400 MPa / 16 km depth

Only the **MIN** composition has been crystallized at this pressure, at 850-900 °C, NNO -2 and for $X_{\text{H}_2\text{Oin}}$ between 1 and 0.6. Results stress the absence of biotite and the ubiquitous presence of pyroxene in experimental phase assemblages, which is clearly inconsistent with natural rhyolites. However, these data are for a temperature range which is too high for the Cotopaxi rhyolites, on the basis of Fe-Ti oxide thermometry and **CHAI** and **WL17** rhyolite phase relations. Therefore, with the available data, we cannot strictly rule out the possibility of rhyolite crystallization at 400 MPa.

5. Discussion

5.1. Storage conditions of the Cotopaxi rhyolitic magmas

According to the natural samples and phase-equilibrium studies, the Peñas Blancas and F-series rhyolites possibly crystallized around 750 °C, $+1 < \Delta \text{NNO} < +2$, at ~200-300 MPa (depth ~7-11 km) and near H₂O saturation (~6-8 wt% after Newman and Lowerstern, 2002; Fig. 11). The presence of sparse amphiboles and pyroxenes inherited from dacitic to andesitic magma raises the question of the origin of plagioclase and biotite in the rhyolites. Yet, none of the andesite phase diagrams show crystallization of An₃₀₋₃₅ or biotite in the *P-T* range of 100-400 MPa and 850-1050 °C, supporting the idea that plagioclase and biotite are cognate crystals of the rhyolitic magma.

The ignimbrites of Colorado Canyon Series and of Chalupas Caldera are more potassic by nearly 2 wt% K₂O with respect to the Cotopaxi rhyolites and, thus, are comparable to the Wangrah **AB421** granite (Klimm et al., 2008; Fig. 2). The **AB421** 200 MPa and NNO phase diagram suggests that the Canyon Colorado Series and Chalupas Caldera ignimbrites could have crystallized at 200 MPa, ~700 °C with a H₂O content close to saturation (~6.5 wt%), i.e., under conditions only slightly different (colder) than those inferred for the Cotopaxi rhyolites.

5.2. Storage conditions of the Cotopaxi andesitic magmas

The andesites define a continuous group from ~57 wt% SiO₂ and ~5 wt% MgO (Mg-andesites) to ~62 wt% SiO₂ and ~2 wt% MgO (Si-andesites; Fig. 2), the least evolved magmas erupting as strombolian type (lava flows and scoria ballistics) and the most evolved

more explosively as pumiceous pyroclastic flows and fallouts. The continuity in the whole-rock data, compositional similarity between Mg-andesite matrix glasses and bulk rock Si-andesites (Fig. 5) plus isotopic constraints (Garrison et al. (2006) suggest that the two andesite types are comagmatic and belong to the same differentiation trend.

The Mg-andesite experiments that best reproduce the Cotopaxi phase assemblage and compositions, i.e. 975-1000 °C and $X_{\text{H}_2\text{Oin}} = 0.5-0.7$, do not allow the discrimination between a P of either 200 or 400 MPa (except for a slight difference in clinopyroxene En content, as also noted for the **TUN** experiments; Andújar et al, 2017). Accordingly, we propose that Cotopaxi Mg-andesites crystallized at T of ~1000 °C, $\Delta\text{NNO} +2$, $X_{\text{H}_2\text{Oin}} \sim 0.5-0.7$, and P from 200 to ≥ 400 MPa (i.e., 7 to ≥ 16 km depth). The H_2O contents of $4.5-6.0_{\pm 0.7}$ wt% measured in the **TUN** charges at 400 MPa, $\Delta\text{NNO} +2$, $X_{\text{H}_2\text{Oin}}$ of 0.5 to 0.7 (Andújar et al, 2017) are in agreement within error with the H_2O -richest glass inclusions showing $\sim 3.5_{\pm 0.7}$ wt% only for the lowest contents. However, the analyzed glass inclusions were trapped in pyroxenes that could have crystallized as well at higher depths or from a more mafic magma, which if necessary does not require a perfect H_2O -content matching between the glass inclusions and the selected experimental glasses. Cooling the Mg-andesite produces Si-andesites. Based on experiments that best reproduce the Cotopaxi phase assemblage and compositions, crystallization temperatures close to 950 °C are suggested, but do not permit constraining pressure between 200 and ≥ 400 MPa.

The Si-andesitic (61-62 wt% SiO_2 and 2-3 wt% MgO) lavas of Morurcu, a Cotopaxi satellite vent whose deposit stratigraphically marks the transition between Cotopaxi I and IIA sequences, contain amphibole, together with plagioclase and scarce clinopyroxenes (Garrison et al., 2011). Thus, the Morurcu magmas could have crystallized in the 200-400 MPa P range, $\Delta\text{NNO} +2$, at slightly lower T (< 930 °C) and higher H_2O contents (> 6 wt%), than the Cotopaxi Si-andesites, in order to stabilize amphibole (Fig. 9). However, further investigation of the phase compositions is necessary to refine the crystallization conditions of the Morurcu lavas.

The contrasted eruptive dynamics of Cotopaxi Mg- and Si-andesites thus rely on composition and temperature differences rather than differences in H_2O contents. Increasing temperature and magnesium content (silicate melt network-modifier) while decreasing SiO_2 content (silicate melt network-former), acts to decrease melt viscosity (Mysen et al., 1982), so that Mg-andesites (~1000 °C, 3-5 wt% MgO, 57-60 wt% SiO_2) are less viscous than Si-andesites (~950 °C, 2-3 wt% MgO, 60-62 wt% SiO_2). Consequently, the Mg-andesites erupt

mostly effusively, as lava or scoria-rich flows, whereas Si-andesites erupt explosively, as siliceous pyroclastic flows and ash fallouts.

5.3. *Petrological relationships between the andesitic and rhyolitic magmas*

Based on isotopic and trace-element data, Garrison et al. (2006, 2011) suggested that crustal contamination is predominant over source contamination in the Cotopaxi magmatic system and that magma evolution is consistent with a crustal assimilation-fractional crystallization process. Their crystal fractionation modelling consistently reproduces the differentiation trend from the least evolved andesites to the rhyolites, starting from an assemblage of amphibole, plagioclase, two pyroxenes, and olivine. Remnants of this primitive magma are likely provided by some highly-calcic plagioclase cores, such as the An₇₈₋₈₈ profile in Fig. 4 (Garrison et al., 2011). Therefore, these authors proposed rhyolite formation by melt segregation from the andesitic mush, with the segregated melt composition spanning SiO₂ contents from 62 to 82 wt%. In the present study, matrix glasses with SiO₂ contents > 74 wt% in Garrison et al. (2011) have been excluded on the criterion that these residual glasses come from microlite-rich andesitic lavas that experienced cooling at sub-surface conditions (i.e., post-storage modifications). This leaves us with matrix glasses in microlite-free or -poor andesitic pumice or scoria ranging from 62 to 71 wt% SiO₂ (Fig. 5 and Pistolesi et al., 2011). We note that ~71 wt% SiO₂ is the composition of glasses in Si-andesite experiments at ~930 °C and 400 MPa (Fig 9). Therefore, natural and experimental glass compositions concur to corroborate the proposition (Garrison et al. 2006, 2011) that fractional crystallization is the main petrogenetic process in the magmatic evolution from Cotopaxi Si-andesites to rhyolites. This conclusion does not exclude sporadic intervention of other mechanisms such as magma mixing, to account for the presence of some inherited crystals in rhyolites.

5.4. *Magma chamber model*

There is limited evidence of intermingling between andesites and rhyolites over the period of time of Cotopaxi activity, such as few andesitic enclaves in rhyolites (Hall and Mothes, 2008) and rare pyroxenes (Garrison et al., 2011) and amphiboles inherited from andesites-dacites in rhyolites. Most mingled samples comprise andesite end-members (e.g. ~58 and ~63 wt% SiO₂ such as in the 1130 AD deposit; Pistolesi et al., 2011), but do not involve rhyolites. This suggests that the reservoirs either do not activate at the same time or cannot

communicate physically (so that ascending andesite would not necessarily enter the rhyolitic reservoir). The latter alternative seems unlikely since transport of the rhyolitic residual melt from the andesite storage region must have necessarily taken place to feed the upper rhyolitic reservoir. There is also evidence for a stationary eruptive conduit over the known eruptive history of the volcano (Hall and Mothes, 2008). Therefore, the former alternative, with both reservoirs not being activated at the same time, is the one preferred here. This implies fluctuations in deep magma fluxes and/or changes in tectonic setting to account for the activation of either reservoir. In particular, the historical period is characterized by spurting andesitic eruptions (frequent and of small to moderate volumes) that may result from frequent magma recharge events that do not allow time for advanced magma differentiation and physical extraction of the residual melt. Such frequent eruptions may be temporarily favored by a tectonic context facilitating andesite ascent from ~16 km below the summit (Fig. 11). In contrast, the early edification stage of Cotopaxi was characterized by large eruptions of mostly rhyolitic magma suggesting that the parental andesitic magma had little opportunity to reach the surface at the time (andesites interbedded in the rhyolitic stratigraphy are scarce). This may result from low or sparse fluxes of magmas recharging the deep reservoir and allowing rhyolitic melt extraction and storage from shallower (~7-11 km) depths (Fig. 11). Thus, cyclic temporal changes in deep magma flux and tectonic setting controlled the possibility of rhyolitic magma extraction and the longevity of the shallow rhyolitic storage reservoir.

5.5. *Present-day plumbing system*

In 2001-2002, 2009, and 2015, Cotopaxi showed noticeable episodes of increasing volcano-tectonic (VT) and long (LP) to very long period (VLP) seismic signals. Classically, VT events are related to fracturing of the medium whereas LP-VLP events are related to fluid movement, either magmatic or hydrothermal. In 2001-2002, VLP signals, located at 3-4 km depth, were observed in the NE flank (Molina et al, 2008). The same kind of VLP signals were described in 2009 by Kumagai et al. (2010) and in 2015 by Arias (2016), being located at 2 km and 2-4 km depth towards the E flank and slightly towards the N of the summit, respectively. The LP signals were interpreted as the resonance of the crack above the magmatic system (Molina et al., 2008) whereas VLP signals may result from the volumetric expansion of the crack due to magma intrusion (Molina et al., 2008; Kumagai et al., 2010; Arias, 2016). By inversion of ground deformation data during the 2001-2002 seismic crises,

Hickey et al. (2015) located a magmatic source at ~4-5 km depth towards the SW flank and reconciled this source of recharge with the seismicity located in the NE flank (Molina et al., 2008) as resulting from fluid migration from SW to NE along fault systems. A magmatic intrusion at ~4-5 km is shallower than estimated here for the rhyolitic reservoir (~7-11 km). However, the presence of pyroxene phenocrysts and dacitic matrix glasses in the 2015 juvenile ash clasts (Gaunt et al., 2016) corroborates the andesitic composition of the magma. Mild deformation on the GPS network recorded through early 2016 and several distal stations showed convincing patterns of outward deformation as a response to a possible deep source over 15 km deep (Mothes et al., 2017). Such a magmatic source location fully agrees with the depth estimates obtained from experimental petrology for the andesites (Fig. 11).

This leaves an important outstanding question concerning the present existence of a shallow rhyolitic reservoir at ~4-11 km below the summit. Indeed, whether rhyolites or Mg-andesites are about to erupt is fraught with consequences regarding risk assessment, since rhyolites have so far erupted much more explosively and voluminously than did andesites. Experimental petrology suggests that rhyolites and andesites may both be stored at shallow depths (i.e., 7-11 km; andesites are potentially stored over much larger – deeper – depth), so that geophysical (seismic and geodetic) data alone may not discriminate between magma – and thus eruption – type. Geochemical monitoring such as analyses of emitted gases and juvenile ashes may provide additional data to predict which reservoir is being activated. For instance, the andesitic nature of the 2015 juvenile ashes makes it likely the present reactivation of the andesitic reservoir, thus ruling out rhyolitic eruptions in a near future.

6. Conclusions

Preexisting phase-equilibrium experiments have been used successfully to interpret Cotopaxi eruption products in terms of magma storage conditions. Although probably not as precise as a set of experiments specifically designed for Cotopaxi volcano, the present approach has the advantage of providing valuable information within a short time in case of volcano reactivation. Based on this approach, we propose that Cotopaxi Mg-andesites (57-60 wt% SiO₂, 3-5 wt% MgO, ~4.5-6.0_{±0.7} wt% H₂O in melt) are stored between 200 and ≥400 MPa (~7 to ≥16 km below the summit), ~1000 °C and ~NNO +2. Cooling of the Mg-andesites by ~50 °C produces the Si-andesites (60-62 wt% SiO₂; 2-3 wt% MgO). Extraction of the residual liquid from Si-andesite crystallization produces the rhyolitic magma (~6-8 wt% H₂O in melt) stored at ~200-300 MPa (~7-11 km below the summit), ~750 °C and NNO +2.

The contrasted eruptive dynamics of Cotopaxi is thus the consequence of different magma compositions and temperatures: the hot Mg-rich andesites erupt effusively as lava or scoria-rich flows, the slightly cooler Si-rich andesites erupt explosively as siliceous pyroclastic flows and ash fallouts, and the rhyolites generate highly explosive pumice fallouts and flows. The Mg-rich andesitic reservoir seems to be active at present, being likely recharged by magma pulses of deep origin. However, sparser or lower deep magma fluxes would allow more time for magma differentiation and residual melt extraction, which could reactivate the shallow rhyolitic reservoir.

ACKNOWLEDGMENTS

We would like to thank I. Di Carlo for help with the SEM analyses. This work benefitted from the financial support of the European FP7_VUELCO project (J. Gottsmann, PI) and Prometeo program from Ecuador (I. Molina, PI).

Fig. 11. Schematic view of the magmatic plumbing system beneath Cotopaxi volcano. Left side: storage of the andesitic magmas at pressures ≥ 400 MPa (≥ 16 km depth), about 1000 °C, NNO +2, and 4.5-6.0 $\pm$ 0.7 wt% H_2O dissolved in the melt in equilibrium with ~30-40% phenocrysts of plagioclase, two pyroxenes, and Fe-Ti oxides. Should this Mg-rich andesite cool by ~50 °C, a silicic andesite is produced. Whereas the Mg-rich andesite erupts effusively (ballistics and lava-and-scoria flows), the more viscous silicic andesite erupts explosively (pyroclastic flows and ash falls). Right side: storage of the rhyolitic magma around 200 MPa (~7 km depth), 750 °C, NNO +2, and 6 wt% H_2O dissolved in a nearly aphiric melt (less than 5% phenocrysts of plagioclase, biotite, and Fe-Ti oxides). The rhyolitic eruptions are highly explosive (Plinian falls and pumice flows). Although the

andesitic and rhyolitic reservoirs are linked by a process of fractional crystallization, Cotopaxi eruptive history suggests reactivation of either reservoir, likely depending on magma flux variations during deep magma recharge. For instance, the recent andesitic eruptions could result from frequent magma recharges that do not provide time for andesite differentiation and rhyolitic melt extraction towards shallower depths. In contrast, past low or sparse fluxes of magma recharge have permitted the generation of rhyolitic magmas.

Highlights

Storage conditions for rhyolitic and andesitic magmas at Cotopaxi volcano, Ecuador, are presented, based on preexisting phase-equilibrium experiments. The approach is meant to provide valuable information within a short time in case of volcano reactivation. We propose that Cotopaxi Mg-andesites (57-60 wt% SiO₂, 3-5 wt% MgO, ~4.5-6.0_{±0.7} wt% H₂O in melt) are stored between 200 and ≥400 MPa (~7 to ≥16 km below the summit), ~1000 °C and ~NNO +2. Cooling of the Mg-andesites by ~50 °C produces the Si-andesites (60-62 wt% SiO₂; 2-3 wt% MgO). Extraction of the residual liquid from Si-andesite crystallization produces the rhyolitic magma (~6-8 wt% H₂O in melt) stored at ~200-300 MPa (~7-11 km below the summit), ~750 °C and NNO +2. The contrasted eruptive dynamics of Cotopaxi is thus the consequence of different magma compositions and temperatures: the hot Mg-rich andesites erupt effusively as lava or scoria-rich flows, the slightly cooler Si-rich andesites erupt explosively as siliceous pyroclastic flows and ash fallouts, and the rhyolites generate highly explosive pumice fallouts and flows. The Mg-rich andesitic reservoir seems to be active at present, being likely recharged by magma pulses of deep origin. However, sparser or lower deep magma fluxes would allow more time for magma differentiation and residual melt extraction, which could reactivate the shallow rhyolitic reservoir.
