Abstract

The present study provides a quantitative way to analyze and interpolate strainfields from ductile fabric field measurements using geostatistics. Based on variogram analysis and kriging interpolations, the developed methodology allows computing automatic cleavage and lineation trajectory maps at different scales from a same field structural dataset. For the example provided by the hot Variscan crust of the Pyrenees, the analysis of cleavage/stretching lineations orientation and kinematic data document pure shear conditions recorded during convergence. Strain was vertically partitioned between an upper crust submitted to homogeneous thickening responding to N-S (orogen-normal) shortening and a hot and partially molten mid-lower crust affected by horizontal longitudinal (orogen-parallel) flow. The emplacement of plutons and gneiss domes generated heterogeneities in the upper crust and induced strain localization into steep anastomosed transpressional shear zones flanking those structures. The results show that geostatistics applied to structural geology are powerful tools for retrieving tectonic regimes of large orogenic segments by identifying and quantifying perturbations in the strainfields induced by protracted and potentially complex tectonic histories. The variogram analysis also gives first order clues to evaluate whether the considered structural domains underwent single continuous ductile or polyphased brittle-ductile deformation.

1. Introduction

Determination of principal strain and stress directions in the lithosphere has always been a key task for understanding and constraining plate tectonics. Mapping and analysis of strain/stress field patterns bring constraints on the mechanical behavior of crust/lithosphere. Such an approach allows evaluating (i) the meaning of spatial shear gradients and finite strain values in terms of displacement(s), (ii) the way deformation localizes, (iii) the role of rheological contrasts between adjacent lithologies during deformation and (iv) the rheological contrasts between structural levels and their degree of coupling. In active tectonic domains, approximate stress fields can be obtained using measured GPS velocity fields (e.g. Welsch, 1983; Kahle et al., 1999; Grenerczy et al., 2000, Zang et al., 2004; Titus et al., 2011) or focal mechanisms from earthquakes (e.g. McKenzie, 1972; Calais et al., 2002; Engdahl and Villasenor, 2002). Structural analyses of fractures and faults further allow retrieving paleo-stress fields (e.g. Angelier, 1984; Blès et al., 1989). For ductile deformation, foliation and stretching lineations can be considered as good proxies of principal strain axes orientations (Ramsay, 1967; Siddans, 1972; Wood, 1974). Foliation and lineation trajectories allow (i) investigating how the direction of principal strain axes change through space and (ii) deciphering homogeneous from heterogeneous strains by considering gradients and trajectory curvatures (i.e., convergence of trajectories) (see Cobbold and Barbotin, 1988). Following Cobbold and Barbotin (1988), the amount of strain is mostly difficult to quantify for natural case, therefore foliation and lineations trajectories – once coupled to a kinematic analysis of fabrics – are used to build paleo strainfields (or strain patterns). These trajectory maps are mostly extrapolated manually on the basis of structural measurements data (e.g. Brun and Pons, 1981; Brun, 1983; Chown et al., 1992; Gautier and Brun 1994; Bouchez and Gleizes, 1995). Moreover, extracting regional trends from individual local structural

65　measurements may not be straightforward and would hardly be reproducible in case of low data

66　density at a considered scale. The resulting trajectory maps may thus be intrinsically qualitative.

67　Considering the limitations of manual strainfields' interpolation, geostatistics can be used to

68　quantitatively analyze spatial variations in the orientation of structural measurements and to

69　obtain the best fitted interpolated maps, whatever the scale considered. The general approach has

70　first been introduced by Matheron (1962). Such geostatistical analysis has already been used for

71　brittle deformation to retrieve stress fields using fracture or fault data set (Escuder Viruete et al.,

72　2003; Rafiee and Vinches, 2008; Koike et al., 2015; Hanke et al., 2017; Riller et al., 2017) and

73　3D modeling of geological objects at local scale (e.g. folds, see Hillier et al., 2013; Grose et al.,

74　2017). It has been also developed and successfully applied to the analysis of ductile fabrics

75　directional data (Gumiaux et al., 2003). Based on a preliminary statistical analysis (the variogram

76　analysis or variography), spatial interpolations can be computed, leading to automatic cleavage or

77　foliation trajectory maps (Gumiaux et al., 2003, 2004).

78　In this study, we apply such geostatistical approach in order to obtain quantitative insights on the

79　way strain has been spatially (i.e. horizontally and vertically) partitioned during convergence.

80　Indeed, in orogenic contexts, geotherms control – at first order – vertical rheological layering and

81　mechanical coupling in the lithosphere (Davy, 1986). Contrary to cold collisional belts such as

82　the Alps and Taiwan (Brun, 2002; Lacombe and Mouthereau, 2002), old accretionary or mature

83　orogens have undergone critical weakening on a lithospheric scale, inducing specific vertical

84　strain partitioning pattern and mass redistribution between the upper crust and a particularly weak

85　lower crust (Chardon et al., 2009). In order to investigate such space-time strain partitioning

86　patterns, the present study focuses on a segment of the Variscides exposed in the Pyrenees, which

87　underwent both thickening upper crust and the laterally flow of its mid-lower crust (Cochelin et

88 al., 2017). In a first step, processing of the overall structural dataset allows producing a strain

89 trajectory map corresponding to the total finite strainfield of this crustal segment. Strainfield is

90 then successively deconvoluted to constrain strain interference effects induced by crustal domains

91 or units of contrasted mechanical behaviors (i.e. the upper crustal metasediments, the mid-lower

92 crust and plutons). The analysis of strainfields based on strain trajectory modeling is performed

93 from regional to local scale, with some focuses made on the Canigou gneiss dome and the Mt-

94 Louis pluton.

95 **2. Geological setting**

96 The Pyrenees form an east-west trending intra-continental mountain range resulting from the

97 collision between the Iberian and the European plates (Choukroune, 1992). During upper

98 Cretaceous to Early Tertiary convergence, shortening was responsible for the exhumation and

99 erosion of the Mesozoic cover, allowing exposure of the Paleozoic basement, which preserves

100 Variscan (i.e., Late Paleozoic) orogenic deformation patterns. This portion of the Variscan

101 orogen corresponds to the foreland of the belt and occupied the core of the Iberian-Armorican

102 syntax during the latest stages of the orogeny (310-290 Ma) (Cochelin et al., 2017). The largest

103 uplifted unit of pre-Mesozoic rocks outcropping in the Pyrenees is called Axial Zone and forms

104 the core and highest part of the Cenozoic belt (Fig. 1a). Differential denudation of the Axial Zone

105 provides an access to a continuous vertical section of the Variscan crust from the shallowest parts

106 in the west (i.e. Carboniferous sedimentary basins) to mid-crustal levels in the east. Despite the

107 "recent" (i.e., Alpine) Pyrenean orogeny, the structural continuity of the Variscan crust is

108 maintained in the Axial Zone; which forms a consistent tectonic domain affected by only local

109 and moderate perturbations due to post-Paleozoic deformation (Zwart, 1986; Carreras and Debat,

110   1996, Carreras and Druguet, 2014, Cochelin et al., 2017, 2018). The present study focuses on the

111   pre-Mesozoic Axial Zone.

112   Figure 1 here

113   The Axial Zone is mainly made of Ediacaran to Upper Carboniferous sedimentary rocks having

114   undergone High Temperature-Low Pressure (HT/LP) metamorphism that induced regional partial

115   melting (Guitard et al., 1996 and references therein). These metasedimentary rocks were intruded

116   from ca. 310 to 290 Ma by large calc-alkaline plutons (Denèle et al., 2014 and reference therein).

117   Two contrasted structural levels are distinguished (de Sitter and Zwart, 1962; Zwart, 1979;

118   Carreras and Capella, 1994). The low-grade metasedimentary rocks belonging to the upper crust

119   are characterized by open to tight EW trending folds and steep N95-110°E striking axial plane

120   cleavage (Figs. 1b & c) bearing steeply plunging stretching lineations (Cochelin et al., 2017,

121   2018). The average strike of cleavage around N100°E associated to an average pitch of lineations

122   around 83°W is compatible with transpression due to ~NS shortening (Cochelin et al., 2017). The

123   lower structural level comprises the partially molten mid-lower crust that appears in gneiss domes

124   elongate parallel to the regional structural trend (Figs. 1a & c) and mostly bearing longitudinal

125   stretching lineations (Carreras and Debat, 1996; Mezger and Passchier, 2003; Denèle et al., 2007;

126   2009; Cochelin et al., 2017). The chronological and structural relationship between steep and

127   shallowly dipping structures has been subjected to debates since the 60's (e.g. de Sitter and

128   Zwart, 1960; Zwart, 1979; Soula et al., 1986; Carreras and Capella, 1994; Carreras and Debat,

129   1996) but recent structural studies, especially within calc-alkaline plutons and gneiss domes,

130   showed that they were formed during a single, protracted period of deformation, under dextral

131   transpressional regime (Bouchez and Gleizes, 1995; Gleizes et al., 1998; Mezger and Passchier,

132   2003; Aurejac et al., 2004; Vilà et al., 2007; Denèle et al., 2007; 2008; 2009; Mezger, 2009;

6

133 Cochelin et al., 2017 among others). In spite of the N-S convergent context, HT-rock of the mid-

134 lower crust were exhumed in gneiss domes (Mezger and Passchier, 2003; Vilà et al., 2007;

135 Aguilar et al., 2015). This has been favored by strain localization near the biotite-andalusite

136 transition, forming retrogressive extensional shear zones (Van den Eeckout, 1986; Van den

137 Eeckout and Zwart, 1988; Mezger and Paschier, 2003; Cochelin et al., 2017) while the core of the

138 domes was affected by horizontal longitudinal flow (Denèle et al., 2007; 2009; Mezger, 2009;

139 Cochelin et al., 2017).

140 Figure 2 here

141 The transition between the thickening upper crust and the laterally flowing lower crust is well

142 exposed in the Central and Eastern Pyrenees by the succession of ~EW trending regional scale

143 synforms and gneiss domes (e.g. the Villefranche syncline and the Canigou gneiss dome, see

144 Figs. 1c & 2). The Canigou gneiss dome is characterized by a pervasive foliation reworking

145 Ordovician plutons turned into orthogneisses and their country-rocks (Fig. 2, Casas et al., 2010;

146 Martinez et al., 2011). Stretching lineations are mainly NE trending in the core of the dome and

147 are associated with dominant top-to-the SW shearing (Guitard, 1960; Soliva et al., 1989; Carreras

148 and Debat, 1996; Cochelin et al., 2017). This massif was lately cut by post-Paleozoic faults like

149 the Alpine Canigou Thrust and the Neogene Têt-Cerdagne and Py-Fillols faults (Fig. 2).

150 Immediately to the north west of the Canigou gneiss dome crops the Mt-Louis pluton, which was

151 emplaced at ca. 301-303 Ma (Figs. 1a & 2) (Denèle et al., 2014). It shows a complex internal

152 structure and can be divided into three subintrusions (Bouchez and Gleizes, 1995) and, like most

153 plutons in the Axial Zone, this pluton was deformed under sub-magmatic to solid-state conditions

154 (Bouchez and Gleizes, 1995; Debon et al., 1996, Denèle et al., 2014). The Canigou and Mt-Louis

155 massifs can be regarded as demonstrative examples of gneiss dome and pluton of the Axial Zone,

156   respectively. Focus analyses of local scale strainfields are made on these massifs in the present

157   study.

158   **3. Methodology and data set**

159   The computation of cleavage trajectory maps results from an interpolation process of the striking

160   value between individual structural measurements. This technique allows imaging the continuous

161   spatial variations of the finite strain field that can be deduced from discrete natural observations.

162   Thereby, some difficulties may arise when measurements (i) are heterogeneously distributed

163   through the area and/or (ii) display significant local-scale variations in orientation. In particular, it

164   is often not straightforward when one has to *a priori* choose whether to highlight local tendencies

165   or regional ones through a hand drawing process, using curvy or smooth trajectories shape,

166   respectively. Here, we employ a geostatistical approach to automatically map both cleavage and

167   lineation trajectories and cleavage dip angle variations from a given field structural dataset.

168   Ideally, interpolations should be made from foliation-lineation pairs in order to integrate the full

169   information of the finite strain ellipsoid's orientation (see the critical review of Davis and Titus,

170   2017). However, such approach requires a very homogeneous dataset in which each lineation

171   trend/plunge measurement can be associated to a foliation strike/dip one and vice versa. In the

172   case of regional-scale studies (as the one exposed here), structural data are often compiled from

173   various types and ages (e.g. digitized maps from PhD theses, articles), and such a prerequisite is

174   unfortunately hardly tenable. Alternatively, structural data sets can be decomposed into four one-

175   dimensional numbers (i.e. strike, dip, trend and plunge) and analyzed separately. While dip value

176   is interpolated using simple kriging on a scalar variable (for a 0-90° range in that case), kriging

177   interpolation of the strike value (which is of circular data type) is performed following the

178   approach developed by Gumiaux et al. (2003). Based on a theoretical and unscaled case study

179 (see Figs 3 & 4), details of the different steps of our approach developed are given below (3.1)

180 and, in particular, some keys for the pre-interpolation variogram analysis (3.2). This synthetic

181 cleavage and stretching lineation dataset simulates interactions between a roughly E-W regional

182 trending structure and termination of an elliptical body, to the west, which may correspond to an

183 intrusion. It results in a triple point as visible in the center of the map (Fig. 3.1).

184 *3.1. Computation of automatic trajectory maps*

185 The computation process has been developed in a GIS environment and all the structural

186 measurements are firstly compiled into a spatial database (37 cleavage orientation measurements

187 in the synthetic case study, with 20 stretching lineations; Fig. 3.1). Secondly, spatial variations of

188 the dataset values can be quantified by the computation of experimental variograms (Figs 3.2 &

189 4.2) (Matheron, 1962). Initially developed for mining purposes and applied to scalar values

190 (Matheron, 1962), this method has been adapted by Gumiaux et al. (2003) for the analysis of

191 circular angular variables such as structural striking data. The goal is to assess the degree of

192 correlation between values of the studied variable (e.g. azimuth or dip of cleavage data) measured

193 at different locations and according to the interdistance separating them. If this correlation degree

194 changes with increasing interdistance, the variable is thus categorized as regionalized. The

195 variogram analysis allows (i) quantifying the maximum distance to which distant data values

196 show significant mutual dependence, (ii) constraining their dependence function to the distance,

197 (iii) deciphering any potential anisotropy in the spatial variations of the regionalized variable and

198 (iv) given the scale of the study area, filtering "regional" and "local" variation trends from the

199 dataset (see details in the next section). In a third stage, kriging interpolation can be achieved on

200 both the dip values and azimuth directions following the method developed by Gumiaux et al.

201 (2003) for circular data. Kriging weights are computed based on a given theoretical variogram

202   model whose equation has been adjusted – for each data set – to the parameters deduced from the

203   detailed variogram analysis (parameters include the function type, the *range* value, the

204   proportional *nugget effect* and *sill* values; see part 3.2 below). In the example, interpolations

205   allow obtaining cleavage direction map, cleavage dip map (Fig. 3.3) or lineation trend maps (Fig.

206   4.3), as continuous grids covering the overall study area, and where corresponding data is

207   available. During the two-fold computation/interpolation of the directional map, the local

208   direction variance can be estimated using the parameter R, which reflects the degree of dispersion

209   of data (Upton and Fingleton, 1989). In [0,1], low R values reflect high variation in measured

210   direction values for short distances, whereas a R of a theoretical maximum value of 1 reflects

211   strictly parallel cleavage directions in the neighborhood (see Gumiaux et al., 2003 and Figs 3.3c

212   & 4.3b). In the example, low R values computed from the cleavage data point to significant

213   directional variations induced by the eastern termination of the elliptical body and its associated

214   cleavage triple point (forming a singular point; see Fig. 3.3c). In contrast, the trend of stretching

215   lineations shows only minor variations for short distances with R values above 0.5 for most of the

216   study area (Fig. 4.3b). Trajectories are then computed, giving a good picture of variation of

217   cleavage directions at the scale of the studied area and reproducing at high resolution cleavage

218   singular points (including neutral or triple points), both within and outside the simulated

219   intrusion, and small scale variations within the elliptical geological body (Fig. 3.4). Besides, the

220   continuous and radial distribution of stretching lineations, as implied by dataset in Figure 3.1, is

221   also well-modeled and imaged following this fully automatic process (Fig. 4.4). In order to better

222   constrain the strain field geometry, trajectory maps can be superposed over the interpolated dip

223   angle map. In the example case study, shallow dipping cleavage areas correspond to the elliptical

224   shape structure to the west and to more scattered cleavage direction zones, as highlighted by

225   rather high R values (compare maps in Figs. 3.4 & 4.4). Note that the low R values obtained in

226 low dip domains may be oversighted compared to those from steep cleavage domains as this

227 analysis of cleavage direction was performed in 2D (i.e. map view). Indeed, strike value of sub-

228 horizontal fabrics (i.e. < 20°) may significantly vary in response to local orientation

229 perturbations.

230 Figure 3 here

231 Figure 4 here

232 *3.2. Variogram analysis*

233 As a general principle, two close data measurements may have more similar values than two

234 distant ones. Yet, superimposed phenomenon at different scales can control variations in the

235 regionalized variable. For instance, cleavage orientation can result from the combination of (i) a

236 tectonic regional-scale maximum shortening direction, (ii) influence of the expansion of a

237 neighboring synkinematic intrusion (medium-scale) and (iii) very local cleavage refraction due to

238 lithological contrast in the rock unit considered. Thus, in order to determine and evaluate the

239 mutual dependence between data values, experimental variograms are calculated as a squared

240 root difference between individual angle values as a function of their separating distance (Figs.

241 3.2 & 4.2); increasing values with distance show decreasing correlation between data values with

242 a rate depending on the steepness. Thus, the shape of the resulting experimental variogram plot

243 gives key information on the spatial structure of the strain field. This is estimated by fitting a

244 theoretical function to the experimental variogram (see continuous grey curves in Figs. 3.2 and

245 4.2) and extracting several parameter values from the latter, as detailed below (see Matheron,

246 1962 for details). Acceptable functions include spherical, exponential or Gaussian.

247   -   An increasing variogram can reach a constant *sill* value for a maximum correlation *range*

248   distance value (Fig. 3.2 left) and is then defined as *stationary*. This shows that the

249   kinematical and/or rheological phenomena controlling the spatial strain variations have a

250   distance of influence shorter than the maximum width of the study area. In the synthetic

251   example, the *stationary* cleavage directions variogram highlights deformation process

252   with effects over 9 to 10 distance units (Fig. 3.2 left). This feature is also consistent with

253   the computed trajectory map which displays the overall structure of the junction area (Fig.

254   3.4). On the contrary, the *non-stationary* variograms computed for the lineation directions

255   or cleavage dip angle show that the phenomenon driving strain orientation's variations

256   has some influence out of scale of the study area (i.e. *range* is not reached, Figs. 3.2 right

257   & 4.2),

258   -   Adjustment and analysis of the trend of the variogram for shorter distances is of primary

259   importance and in particular its initial slope characterizing the type of influence linked to

260   the phenomenon. Exponential function (Fig. 3.2 left), for instance, displays a notably

261   quick increase from its original. This corresponds to continuous spatial variations in the

262   strain direction but with a rather limited size (or rapid decrease) of influence. In the

263   synthetic example, such feature is attested to by the narrowness of triple junction's zones

264   and rather high curvature of the trajectories there (Fig. 3.4). In contrast, the Gaussian

265   theoretical variogram function displays a nearly null slope from its origin (Fig. 4.2)

266   showing a very slow decrease of influence of the phenomenon in space. This is expressed

267   in the strain field by low curvature and very smooth variations in the trajectories pattern

268   (Fig. 4.4).

269   -   Finally, a non-null ordinate value at the origin of the variogram – the *nugget-effect* –

270   reflects some variations in the strain field that cannot be considered regarding the given

271 density of the data points. This includes a proportion of either background noise in the

272 dataset (i.e. different kinds of uncertainties or errors made during the acquisition process),

273 very local rheological effects (such as cleavage refraction in layered rocks for instance)

274 that can be regarded as insignificant at the scale of the strain field considered, or both. In

275 the synthetic case study presented here, the variogram computed for stretching lineations

276 direction measurements displays a null *nugget effect* (original variogram Γ is zero, Fig.

277 4.2). This corresponds to an idealistic situation where neither measurement error nor very

278 local deviation effects exist in the dataset and 100% of the cleavage direction variations

279 can be modeled in the trajectories map computation. For natural case studies, a significant

280 proportion of the variance may be included in the *nugget* and, thus, not modeled.

281 In order to detect potential anisotropy in strainfield variations, *directional* individual variograms

282 can be calculated by selecting data pairs along predefined space direction classes. This technique

283 is particularly efficient (i) to quantify the *range* of significant variations of values in the

284 investigated directions and (ii) to highlight main structural anisotropies such as folds or sigmoidal

285 trends induced by regional shearing (Gumiaux et al., 2003, 2004, Branquet et al., 2012).

286 *3.3. Data set*

287 All the structural data available to date in the Axial Zone of the Pyrenees (Cochelin et al., 2017)

288 have been treated. This extensive structural compilation (see supplementary materials) comprises

289 14 275 cleavage and foliation plane measurements, including 12 665 with dip information and

290 only 1 623 mineral-stretching lineations. At first, analysis and interpolation of structures'

291 orientation is performed for the entire dataset over the Axial Zone. Then, in order to deconvolute

292 the finite strain field, three distinct structural sub-sets have been selected based on the type of

293 geological units in which structural measurements have been made: (i) a first set for the upper

294 crustal metasedimentary rocks called hereafter 'upper crust' comprising 5 366 cleavage planes

295 and 272 stretching lineation measurements, (ii) a second set for the plutons comprising 3610

296 foliation planes (with a zoom on the Mt Louis pluton) and (iii) a third set for mid-lower crustal

297 rocks called hereafter 'mid-lower crust' including 5 299 foliation planes and 1 351 mineral-

298 stretching lineation measurements (with a zoom on the Canigou gneiss dome). Spatial selection

299 have been made using digitalized outlines of the corresponding units in the maps.

300 Cleavage/foliation data points are spatially duly distributed over the Axial Zone (see

301 supplementary materials) and the strikes show a normal distribution centered on N96.5°E and a

302 skewness factor of about 0 (nonparametric skew used here; Fig. 5a). Cleavage strikes from the

303 mid-lower crust follow a very similar normal distribution (Fig. 5b) with a mean value at N94.6°E.

304 In contrast, the directional data from the upper crust are skewed to the left and show a mean value

305 of N102°E (Fig. 5c). For the whole Axial Zone, the dip values of cleavage/foliation data show a

306 mean value of 51° and a skewness around 0 (Fig. 5d). In the middle crust, dip values also show a

307 skewness about 0 with a mean value of 47° (Fig. 5e) while data in the upper crust are skewed to

308 the steep values and show a mean value of 51° (Fig. 5f). In the whole data set, flat-lying

309 foliations (i.e. $< 20°$) represent less than 7% of the measurements. Therefore, their relative impact

310 on interpolations of strike values can be considered as negligible in the present case study.

311 Stretching lineations have principally been measured in gneiss domes. Considering their data

312 points' spatial distribution, geostatistics were applied to mid-lower crust and solely statistics for

313 upper crust data.

314 Figure 5 here

315 **4. Results**

316 *4.1. Axial Zone strain field*

317 The omni-directional variogram for the Axial Zone dataset displays a sill reached for a 10km

318 general range value (grey dots/black curve, Fig. 6a). An abrupt change in slope at 1.8km indicates

319 a second, intermediate range, which indicates the change to a different structuration, from local to

320 more regional scale phenomenon effects. As a whole, this variogram can be modeled with (i) a

321 nested (or imbricated) structure of two spherical functions of distinct range values and (ii) a

322 global sill of 1095 square degrees and a nugget-effect value of 503 square degrees (corresponding

323 to 46% of the total variance for this dataset).

324 The omni-directional variogram obtained for dip measurements over the Axial Zone shows an

325 exponential trend, reaching a sill of about 480 square degrees at a 21 km range and showing 60%

326 of proportional nugget effect (grey dots/black curve, Fig. 6b). The later suggests, on average, a

327 significant variability of the dip values measured over short distances (i.e. distances shorter than

328 1 km).

329 Figure 6 here

330 Based on the variograms (Fig. 6a), interpolation of cleavage trajectories at the scale of the whole

331 Axial Zone was performed using a 10km range. In this case, the interpolated trajectories display

332 an average N100°E parallel trend over most of the Axial Zone and rotates to an average of

333 N130°E in eastern part of the Axial Zone (Fig. 7a). Based on the R parameter map (Fig. 7b),

334 domains belonging to the upper crust show limited cleavage strike dispersions (with R values

335 above 0.5). This is also shown by the regular trend of the trajectory map in the upper-crust

336 domains and especially in a ~30km wide N-S corridor displaying sub-parallel trajectories in

337 Central Pyrenees (Fig. 7b). This corridor is devoid of plutons (see Figs. 1b & 7a), suggesting a

338 role of such intrusions in local- to intermediate-scale variations of the upper crust strainfield.

339   Figure 7 here

340   Interpolation of cleavage dip values for the whole Axial Zone dataset (Fig. 8a) displays a clear N-

341   S segmentation, with steep cleavage in a northern domain and shallowly dipping cleavage in a

342   southern domain. This N-S fanning of cleavage dip is well expressed, especially in the ~N-S

343   corridor of sub-parallel trajectories referred to above (Fig. 7b). This variation corresponds to the

344   fan of cleavage that had been early noticed by Zwart (1979) in this region. Calculation of the

345   gradients between interpolated dip values (Carrara et al., 1991) allows identifying zones or bands

346   with rough variations of dip, and, in another hand, undisturbed domains such as in the upper crust

347   level (Fig. 8b; note in particular the delineation of the ~NS corridor in the central part).

348   At second order, the strain field appears rather heterogeneous. Gneiss domes and plutons are very

349   well individualized and evidenced by circular to concentric trajectories (Fig. 7a). Heterogeneity is

350   also highlighted by converging and tightening of the trajectories underlining at least 5

351   longitudinal 100 to 150 km long shear zones. They mostly trend ~N100°E and locally N130°E,

352   where they wrap around gneiss domes and plutons. Trajectories that converge in N100°E

353   trending bands show rather symmetrical pattern with both clockwise and counterclockwise

354   rotations on both sides of these bands. In contrast, N130°E trending bands induce convergence

355   and bending of trajectories as smooth sigmoids. Such sigmoidal patterns (i.e. asymmetrical) for

356   trajectories are compatible with dextral shearing (Fig. 7a) (Ramsay and Graham, 1970). These

357   sigmoidal patterns form locally asymmetrical singular points (neutral or triple points) at western

358   and eastern tips of elliptical bodies (e.g. around the Néouvielle pluton), which is also compatible

359   with dextral shearing. Otherwise, cleavage singular points at eastern and western terminations of

360   the domes and plutons appear mainly symmetrical in respect of the elongation axe of these domes

361   and plutons.

362 Figure 8 here

363 Thus, the upper-crustal cleavage appears disturbed only around granitic plutons with particularly

364 low R values coinciding with (i) cleavage singular points and (ii) some known composite plutons

365 showing internal imbricated magmatic structures (e.g. Cauterets plutons, Fig. 7b). In the eastern

366 part of the Axial Zone, high dispersion zones (i.e. with low R values) surround the gneiss domes.

367 Some folded gneiss domes display internal dispersion too (e.g. the Aston gneiss dome, see

368 Denèle et al. 2009). Discrete dispersion bands, sometimes oblique to the cleavage trajectories, are

369 also mapped within gneiss domes, like in the Canigou (Fig. 7b). This kind of dispersion could be

370 related to post-Variscan faulting (see section 4.4).

371 The impact of gneiss domes and plutons on the regional strainfield is also well shown by

372 cleavage dip variations (Fig. 8b) outlining concentric shapes and reflecting short-length gradients

373 between the cores and envelops of these bodies (e.g. the Cauterets plutons). Other short-

374 wavelength variations that are not directly related to domes or plutons display highly to slightly

375 oblique trends to trajectories. For instance, N60° to N80°E trending bands are detected south of

376 the Canigou gneiss dome. This reflects late tilting of the cleavage along Neogene normal faults as

377 well as Alpine thrusts (Fig. 8b). The relative scarcity of such perturbations shows that the

378 Variscan structures are only weakly affected by post-Paleozoic deformation phases within the

379 Axial Zone (see Cochelin et al. 2017, 2018).

380 As a whole, the overall strain field looks homogenous on a regional-scale and locally disturbed

381 by the presence of gneiss domes and plutons, forming areas with curved cleavage trajectories and

382 lower dip values (e.g. in eastern Axial Zone).

383 *4.2. Upper crust*

384   The omni-directional variogram computed for the upper crust dataset (blue dots/curve, Fig. 6a)

385   shows an exponential trend with a significantly lower variance (849 square degrees) than that of

386   the entire data set, but a similar nugget effect proportion (47%). The best-fitted theoretical

387   variogram suggests an intermediate range at ca. 5 km. The four directional-variograms display a

388   same trend than the omni-directional one (compare Figs. 6a & 9a, b) with similar range (5km),

389   sill (810 square degrees) and proportional nugget effect (between 47 and 53%) values. The NE-

390   SW (i.e. from N22.5° to N67.5°E) trending directional-variogram differs from the others, with a

391   sinusoidal trend of periodicity around 18 km. This illustrates systematic regional scale

392   undulations of directional data, along the NE-SW direction (i.e. forming perpendicular ~NW-SE

393   striking bands like).

394   Figure 9 here

395   Considering cleavage dip values in the upper crust, the omni-directional variogram is similar to

396   that of the entire Axial Zone dataset but tends to show a greater instability (blue dots/curve, Fig.

397   6b). Directional-variograms are calculated from dip measurements parallel and perpendicular to

398   the average cleavage strike (i.e. ~N100°E, Fig. 9c). The "parallel" N100°E directional-variogram

399   has an exponential trend with a 5km range (much shorter than for the omni-directional

400   variogram) and a proportional nugget effect around 52%. In contrast, the "perpendicular" N10°E

401   oriented directional variogram (Fig. 9d) displays an exponential trend but is non-stationary (it

402   does not reach a sill up to the maximum possible 40 km computational distance). The latter

403   depends on the N-S width of the Axial Zone and on the critical number of data pairs available for

404   calculation, which dramatically decreases beyond 40km and makes the variogram unstable (Fig.

405   9d). These two directional-variogram show that cleavage dip value does not have regional-scale

406   variations along strike in the upper crust, whereas such variations are evidenced in the N-S

407   direction, perpendicularly to the fabric. Following the exponential best fit function on the 40 first

408   kilometers, the range of the N-S directed variogram and the characteristic distance of influence of

409   the corresponding phenomenon could be reached around 80-100km. This variation can be related

410   to the regional N-S fan of schistosity (section 4.1).

411   Interpolations of cleavage directions have been performed up to 20 km interdistance, which

412   corresponds to the largest range revealed by the variogram analysis of the upper-crust (i.e. in

413   directional variogram, Fig. 9a). Regional trajectories computed from the sole upper crust are

414   roughly parallel. They display an overall arc shape (Fig. 10a) from N110°E trends in the western

415   part of the Axial Zone, longitudinal trends in the central Axial Zone to N130-140°E trends in the

416   easternmost Axial Zone, which is quite similar to trajectories obtained in Fig. 7a. At second

417   order, E-W elongated lens patterns can be deciphered in the Eastern Axial Zone. In the western

418   Axial Zone, trajectories are weakly disturbed and only display a few variations over short (<10

419   km) wavelength undulations. The convergence of N110°E trending trajectories in the median part

420   of the Axial Zone (e.g. between Ct and Nv) and disappearing to the east is the only apparent

421   regional strain gradient revealed by the interpolation (Fig. 10a). Indeed, the rather consistent

422   spacing of the trajectories indicates a more homogeneous strain pattern than obtained using the

423   entire data set (Fig. 7a). Similarly as on the first trajectory map, singular points are symmetrically

424   displayed at western and eastern tips of the 10 to 20 km elliptical bodies and aligned along the

425   cleavage mean trend (Fig. 10a). The only asymmetrical converging pattern (i.e. sigmoidal) of

426   trajectories are located, from west to east, around the Chiroulet-Lesponne domes (CL), the

427   Néouvielle plutons (Nv) and the eastern part of the Canigou dome (Ca) (Fig. 10a). These

428   sigmoidal trajectories again suggest dextral shearing within shear bands.

429   Figure 10 here

430   The interpolation of cleavage dip values for the upper crust data set upholds a NS segmentation

431   over the Axial Zone (Fig. 10b) with a northern part showing steep to vertical cleavage and a

432   southern one where the cleavage is progressively tilted southward to reach moderate to low

433   northward dips. In the Eastern Axial Zone, this segmentation of cleavage dip is still visible but is

434   disturbed by the influence of gneiss domes and plutons (compare Figs. 1a & 10b). In central and

435   western Axial Zone, the influence of Bossost and Chiroulet-Lesponne domes is also documented

436   by two "anomalies" of shallowly-dipping cleavage inside the northern steeply-dipping domain

437   (Fig. 10b). Even though only the upper crust structural dataset is considered in the present

438   interpolations, both cleavage trajectories (showing lens shapes map structures) and interpolated

439   dip map display anomalies surrounding gneiss domes and plutons (compare Figs. 7 & 10).

440   Whatever the cleavage dip, stretching lineations measured in the upper crust are, in most cases,

441   characterized by high pitch values (>60° for 61 % of the set). As cleavage is mostly steeply

442   dipping (Fig. 1b & 10b), lineations often have high plunges. In regional shear zones (Figs. 1 &

443   7a), lineations are associated with either dip-slip or reverse sense of shear with minor dextral

444   component (Cochelin et al., 2017, 2018). If plotted in a Dip-Pitch-Plunge ternary diagram (Fig.

445   11-left; see Chardon et al., 2009), two distinct sub-populations are identified. Most of the dataset

446   shows a trend from the vertical flow to the horizontal flow pole, which reflects a decrease of

447   foliation dip with nearly constant high pitch values. The remaining part of the data is closer to the

448   Orogen-parallel "strike-slip" flow pole, reflecting lower pitches on steep planar fabrics (Fig. 11-

449   left). At very first order, the upper-crust is thus characterized by (orogen-normal) horizontal

450   shortening and (sub-) vertical stretching. In more details, variations from the vertical to the

451   horizontal flow poles can be related to (i) the regional-scale N-S segmentation of the upper-crust

452   strain in two main cleavage dip domains (Fig. 10b) or (ii) the shallowing of upper crust cleavage

453   around the domes (e.g. the Bossost dome and the Canigou dome, Fig. 10b). Furthermore, at a

454   third order, the dispersion of the data between the vertical flow pole and the orogen parallel

455   "strike-slip" flow pole (left axis of the triangle plot) reflects strain partitioning within strike-slip

456   dominated transcurrent shear zones. In the Axial Zone, these shear zones – mainly N120-130°E

457   trending – show dextral-reverse kinematics and are flanking gneiss domes and plutons (Cochelin

458   et al., 2017; e.g. the Mérens and Têt shear zones; Fig. 7a).

459   Figure 11 here

460   *4.3. Upper crustal plutons: focus on the Mt Louis massif*

461   The omni-directional variogram computed from the fabric direction measurements in the Mt

462   Louis pluton (extracted from Anisotropy of Magnetic Susceptibility - AMS - foliation orientation

463   extracted for each station of Bouchez and Gleizes, 1995) is stationary (Fig. 12a): it reaches a

464   1142 square degrees sill at 3.4 km range and includes 54% of proportional nugget effect. The

465   global cleavage direction variance for this pluton (corresponding to the sill) and its variability at

466   very short distances (the nugget) are similar to those obtained for the global omni-directional

467   variogram computed for the entire Axial Zone (Fig. 6a). This suggests that this massif – and

468   certainly plutons in general – are of prime importance in the structuration of the strainfield. Yet,

469   the Mt Louis experimental variogram displays a distinct range value and follows a Gaussian trend

470   (with flat behavior close to the original) corresponding to particularly smooth tendency variations

471   of the cleavage directions at the scale of the pluton. The regional interpolation (Figs. 7a & 12b)

472   over the Mt Louis pluton and its wall rocks is characterized by longitudinal trajectories on the

473   central-western part of the pluton with large and smooth undulations, whereas the concentric

474   trajectories inside the pluton is only and roughly evidenced in its eastern part. As expected, the

475   resulting interpolated trajectories at local-scale are more sensitive to local variations than those

476   obtained with larger range parameters (compare Fig. 12b & c). The sub-massifs are well

477   individualized by concentric trajectories patterns, as exemplified in its western and eastern parts.

478   These concentric patterns are in agreement with the trajectories obtained manually by Bouchez

479   and Gleizes (1995) (Fig. 12d). Furthermore, our interpolations looks delineating three NW-SE

480   bands showing asymmetrical converging trajectories (s-shape sigmoidal structures) coinciding

481   with dextral shear zones inferred by Bouchez and Gleizes (1995) (Fig. 12d). Even though

482   interpolated sigmoids are compatible with apparent dextral shearing (Fig. 12c), trajectories

483   display very smooth variations and non-localized/pervasive shearing.

484   Figure 12 here

485   *4.4. The lower crust and focus on the Canigou dome*

486   The omni-directional variogram of the mid-lower crust exposed in the domes displays, as a

487   whole, a slightly higher variance (i.e. average sill) and higher proportional nugget effect values

488   (50%) than for the entire Axial Zone dataset (orange dots/red curve Fig. 6a). It shows a nested

489   structure with (i) an exponential evolution up to 6-7 km and, beyond, (ii) a sinus trend of 15-20

490   km periodicity around the average sill (Fig. 6a). Such a rhythmic variogram can be related to the

491   peculiar spatial distribution of measurements, which form evenly spaced clusters centered on the

492   gneiss domes. The periodicity may thus simply reflect the average size of these domes, which is

493   known as a hole-effect.

494   Focusing on the Canigou dome, the local-scale omni-directional variogram computed for

495   cleavage striking data is stationary. It displays a lower maximum range (5 km) and a lower

496   proportional nugget value (~38%) than the regional-scale one (compare Figs. 6a & 13a). This

497   indicates less variable cleavage orientations and thus a more consistent strain field when focusing

498 on the lower-crust. The variogram follows an exponential trend corresponding to a rapid

499 decreasing effect of the phenomena with distance. The interpolated foliation trajectories reveal

500 two half domes (Fig. 13b), with E-W hinges. Considering the R parameter (Fig. 13c), the contact

501 zone between the two sub-domes coincides with a N50°E to N80°E trending band of highly

502 dispersed cleavage directions. The high-R band actually coincides with the Neogene Py-Fillols

503 normal faults, which cross-cuts the gneiss dome. Besides, the low-R domain at the south-eastern

504 boundary of the dome also appears to be related to post-Variscan faults and reflects the local

505 impact of the South Canigou Alpine thrust (Fig. 2) as suspected from the regional-scale map (Fig.

506 7b).

507 Figure 13 here

508 The stretching lineations measured within (Fig. 14a) the Canigou dome display only limited

509 variations in direction. The omni-directional variogram (Fig. 14b) is characterized by a high

510 ~57% proportional nugget effect and is defined by a sinusoidal trend. The interpolated

511 trajectories of stretching lineations exhibit an overall NE-SW trend (in red, Fig. 14c), with a very

512 smooth pattern. In contrast to the cleavage measurements, lineations do not show disturbance that

513 could be related to post-Variscan faulting. Indeed, the Py-Fillols faults are sub-parallel to the

514 lineation trajectories and the latter thus look poorly affected by late brittle deformation. First

515 order stretching trajectories are oblique on the hinge of the dome (compare Figs. 13b & 14c). In

516 greater details, trajectories display a systematic and progressive curvature, stretching becoming

517 progressively more transverse along the dome's limbs than in its core. This defines a map radial

518 trend from NE-SW in the lowermost structural levels of the dome to a NNE-SSW direction in the

519 southern limb and up to NW-SE trend in its north-western part. This latter trend is not well

520 expressed because the northern flank of the dome is actually truncated by the Neogene Têt-

23

521 Cerdagne fault (Fig. 2). As a whole, interpolated cleavage and lineation trajectories within the

522 Canigou massif thus look particularly smooth and continuous; cleavage is only disturbed by

523 significant but quite local effect of recent faulting.

524 Figure 14 here

525 Considering the overall Axial Zone, the average stretching direction is c.a. N98°E in the mid-

526 lower crust (Fig. 15a) and, in a Dip-Pitch-Plunge diagram, data are clustered close to the orogen-

527 parallel horizontal flow pole (Fig. 11-right). Dispersion of lineations towards the orogen-parallel

528 "strike-slip" flow pole (Fig. 11-right) must be due to the late amplification of gneiss dome by

529 folding, producing steep to overturned southern limbs in some cases (see Denèle et al., 2007,

530 2009, Vilà et al., 2007, Cochelin et al., 2017). In greater details, stretching lineations display two

531 distinct direction families with regard to the gneiss domes' cartographic long axes. Longitudinal

532 to slightly oblique stretching/flow is dominant, representing ca. 90% of the measurements within

533 the domes (see the above described focus on the Canigou). Transverse stretching directions (i.e.

534 NS trends) are restricted to the domes' envelope and represent only 10% of the exposed middle

535 crust (Figs. 15a & 15b). In details, oblique WNW-ESE to NW-SE trends are documented in the

536 core of all gneiss domes from the northern and western parts of the Axial Zone (i.e. Aston, Lys-

537 Caillaouas, Bossost, Chiroulet and Lesponne domes) and from the Albères massif to the East

538 (Fig. 15b). Purely longitudinal stretching is restricted to the Hospitalet dome while the Canigou

539 shows a specific ENE-WSW trend (Figs 15b). Transverse stretching directions are observed in

540 the envelope of the Chiroulet, Aston and Canigou domes and can be noticed in the Bossost dome

541 (Fig. 15b). In the Chiroulet and Aston, the transition between longitudinal and transverse

542 direction of stretching is abrupt, whereas it appears to be more gradual from the core to the limbs

543 of the Canigou, Hospitalet and the Bossost domes (Fig. 15b). We consider the direction of

544 stretching in the core of gneiss domes as representative of the deep flow within the crust while

545 direction of stretching in domes' envelope is related to their exhumation (Cochelin et al., 2017).

546 **5. Discussion**

547 *5.1. Strain partitioning and crustal flow in the Variscan crust of the Pyrenees*

548 The variogram calculated for the upper crust is stationary and shows the minimum of all the

549 global variances (i.e. *sill* values) calculated in this study (compare variograms in Fig. 6). Such

550 features reflect an overall steady strain direction throughout this domain, which bears the regional

551 structural grain (Fig. 7a). Regional-scale interpolated cleavage trajectories for the upper crust are

552 longitudinal and roughly collinear (Fig. 10a), which is typical of homogeneous deformation

553 (Choukroune et al., 1995). Such cleavage trajectories pattern coupled with a dominant steep

554 stretching (Fig. 11-left) is compatible with a bulk pure shear dominated deformation regime

555 (Tikoff and Greene, 1997; Teyssier and Tikoff, 1999) with ~N-S horizontal shortening and

556 subvertical principal stretch (Cochelin et al., 2017, 2018).

557 The partially molten mid-lower crust is observed in domes (Fig. 1a). The interpolated foliation

558 trajectories, both at regional and local scales (see Figs. 7a & 13b), display circular to concentric

559 trajectories within and around the domes. At regional scale, the ca. 15-20 km periodicity in the

560 cleavage striking variations observed in the experimental variogram (Fig. 6a) shows that the

561 domes display almost constant widths and could represent the periodical average map

562 interdistance between them. We infer that this is related to a mechanical instability effect in the

563 Variscan crust during original doming and exhumation of mid-lower crust. Smooth cleavage and

564 lineation trajectories within gneiss domes (e.g. the Canigou massif) point to a rather

565 homogeneous strainfield in the mid-lower crust with mainly longitudinal to slightly oblique

566 stretching (Fig. 15) within domes' core.

567   Figure 15 here

568   In order to study the transitions from the upper crust to the mid-lower crust strains, one must

569   consider the overall cleavage measurements dataset. At first glance, the nested structure of the

570   regional-scale experimental variogram (Fig. 6a, grey dots/black curve) suggests that the Axial

571   Zone includes distinct strainfields. Indeed, when considered separately, the cleavage

572   measurements from the upper- and the mid-lower crust give two different variograms with

573   distinct trends and parameters (Fig. 6a). Yet, if the two strain fields evidenced would display

574   directions cross-cutting relationships (in particular within the contact/transition zones), the

575   variogram computed for the overall data (in black, Fig. 6a) would display a significantly higher

576   *nugget* value than the two others taken individually; which is not the case here. Besides, cleavage

577   of the upper-crust has very steady orientations (i.e. both in strike and dip) and a dominant

578   longitudinal collinear trend across the overall Axial Zone but some "disturbances" are linked to

579   the gneiss domes. Thus, the finite strain orientation of upper-crust is dependent on the mid-lower

580   crust fabric orientation when approaching domes' envelops, suggesting coeval deformation.

581   While shallow parts of the Variscan crust of the Pyrenees was affected by homogeneous

582   thickening, the mid-lower crust was contemporarily affected by homogeneous longitudinal

583   stretching (Figs 11 & 15) reflecting lateral horizontal flow, which is also compatible with NS

584   horizontal shortening. This suggests vertical coupling during deformation (Tikoff et al., 2002).

585   As proposed by Cochelin et al. (2017), such a vertical strain partitioning is typical of hot and

586   ultra-hot orogens, where lithosphere has been significantly weakened (Cagnard et al., 2006a,b,

587   Cruden et al., 2006, Chardon et al., 2009).

588   When considering the overall cleavage direction dataset – including upper-crust, plutons and

589   gneiss domes – the interpolated trajectory map underline a quite heterogeneous pattern, with

26

590   strain localization into regional scale, anastomosed longitudinal bands (Fig. 7a). These bands

591   correspond to dextral-reverse shear zones observed in the field and mapped (e.g. Carreras, 2001;

592   Cochelin et al., 2017). The localization of these anastomosed shear zones seems to be intimately

593   linked to the emplacement of gneiss domes and syn-kinematics plutons, as shear zones border

594   these massifs (Fig. 7a). Domes and plutons must have acted as regional heterogeneities while the

595   crust was affected by NS horizontal shortening. Therefore, we consider that these regional shear

596   zones nucleated because of the emplacement of domes and plutons – themselves driven by

597   mechanical instability during regional-scale shortening. Such an interpretation is further

598   supported by geochronological and field structural studies arguing that steep shear zones were

599   activated during and after the emplacement of gneiss domes and plutons (Vilà et al., 2007;

600   Denèle et al., 2007; 2009; Druguet et al., 2014; Cochelin et al., 2017; Van Lichtervelde et al.,

601   2017).

602   At second order, directional-variograms computed for the upper-crust (Fig. 9a) document ~15-

603   20km periodical undulations of the cleavage directions following a NE-SW spatial direction.

604   Likewise, the corresponding interpolated trajectories display asymmetrical strain gradients

605   (sigmoidal undulations) compatible with a dextral component of simple shear along few N120-

606   140°E trending bands (Fig. 7a), which are characterized by domains of more shallowly plunging

607   lineations (Fig. 11-left). Nevertheless, these bands appear poorly significant at regional scale as

608   the trajectories are mostly collinear and symmetrical. Thus, these undulations reflect horizontal

609   strain partitioning in response to the emplacement of local heterogeneities in a more

610   homogeneous general strainfield.   Therefore, our results show that the dextral shearing

611   component of deformation has been over- stressed in previous studies because most of them were

612   focused on syn-kinematic plutons, and had had a minor impact on the strainfield.

613   *5.2. The variogram analysis, a tool to investigate the rheological behavior of the crust*

614   As a preliminary step, the variogram calculation and analysis is critical to detect and quantify

615   significant variations (including the maximum correlation distance, variance and behavior at

616   short distances) of the studied *regionalized variable* as well as potential anisotropy. We propose

617   hereafter that, whatever the scale considered, the best fitted trend of variograms can be used to

618   characterize the rheological behavior or the tectonic history of the geological object/domain

619   investigated.

620   Amplitude of the variations in the measured values is evaluated by the *sill* (general variations;

621   variance) and the *nugget* values in an experimental variogram. On the other hand, whatever those

622   variations, the behavior to the origin of the variograms allows quantifying the way the variable

623   varies with distance. In this study, gaussian or sinusoidal variograms have been computed for

624   structures such as syn-kinematic plutons and gneiss domes. The very low original slope of these

625   variogram functions points to limited and very progressive variations between structural

626   orientation measurements, as exemplified by the Mt-Louis pluton and the Canigou gneiss dome

627   (Figs. 12a & 14b). Indeed, the Mt Louis pluton, displays highly continuous and progressive strain

628   variations and non-localized simple shear corridors. As shearing of the pluton happened during

629   its cooling (Bouchez & Gleizes, 1995), we argue that the trend of the corresponding variogram

630   can be diagnostic of such homogeneous/continuous deformation through time in case of weak

631   mechanical behavior such as cooling magmas (Fig. 16). Similarly, in the Canigou gneiss dome,

632   stretching lineations formed during pervasive metamorphism and crustal flow show continuous

633   and smooth variations in trends, as illustrated by a sinusoidal variogram (Fig. 14b). To us, this

634   phenomenon may also reflect a continuous ductile deformation at high temperature, which

635   remains undisturbed during late Variscan folding and post-Paleozoic faulting (Fig. 16).

636   Figure 16 here

637   Exponential or spherical variogram trends – with a significantly high original slope – correspond

638   to a fast decorrelation between data point values with distance. We thus argue that geological

639   objects or structural domains characterized by such variogram trends have experienced less

640   homogeneous deformation or a polyphased tectonic history. Indeed, zooming on the Canigou

641   dome shows that variations of cleavage directions are mainly disturbed by post-metamorphic

642   structural discontinuities (i.e. faults). Such discontinuities may induce the modification of an

643   initially sinusoidal or gaussian variogram trend – as witnessed by the lineations dataset – into a

644   typically disturbed variogram (i.e. exponential trend), as illustrated in Figure 16. At regional

645   scale, the cleavage orientations from the whole upper crust (metasediments) reflect interferences

646   between a regional and consistent trend and the domes and plutons. For upper crust, the

647   corresponding variogram clearly displays an exponential trend with a quite short *range* distance

648   (Fig. 16). Domes and plutons can be regarded as geological discontinuities in the upper crust,

649   explaining the exponential variogram trend for the upper crust dataset (Fig. 16) and the resulting

650   interpolated trajectories showing local bending and reorientations around them (Fig. 10). Finally,

651   the spherical trend of the omnidirectional-variogram that characterizes the whole Axial Zone

652   reflects multi-scale interferences in a homogeneous strainfield recorded through time in the

653   basement. This variogram corresponds to the imbrication, the convolution of all the variograms

654   including local to regional variations induced by all the geological and structural objects/domains

655   that compose the exposed crust (Fig. 16).

656   **6.   Concluding points**

657   The present study shows that geostatistics is a powerful tool to model continuous strain

658   trajectories from local ductile structure measurements. This inversion method can be considered

659   as alternative and complementary to forward analog or thermo-mechanical modelling to

660   investigate strainfields and the interplay of different mechanical controls leading to the

661   development of finite strain in the crust. In particular, this study shows that the approach

662   developed allows:

663   - Separating (i) significant local to regional variations in strainfields from (ii) variations

664   that cannot be considered and modeled from structural data. Variogram analysis allows

665   determining the spatial scale (maximum distance) of influence of the tectonic and/or

666   rheological controls on strain spatial variations. To the opposite, background noise or very

667   local variations are integrated to the nugget effect and not modeled in computed

668   trajectories for instance. At the scale of the Axial Zone of the Pyrenees, such non-

669   significant variations make ~50% of the total variance of the dataset.

670   - Investigating strainfields at different scales, from a same structural dataset. By separating

671   trends which are significant at a given scale from variations regarded as some noise or too

672   "local", different sub-scales can thus be explored within a study area. When zooming on

673   very local sub-domains, variations initially considered as "noise" in the regional-scale

674   nugget effect can become significant and be interpreted. In the case of the Pyrenean Axial

675   Zone, local interpolated map of the Canigou gneiss dome or Mt-Louis pluton display

676   more detailed trajectories than at regional-scale, where internal variations can be regarded

677   as irrelevant.

678   - Deconvoluting juxtaposed strainfields. Nested structures of experimental variograms

679   point out combined effects of different imbricated phenomena. The variogram analysis of

680   data sub-sets, for distinct structural domains, allows quantifying their relative impact on

681   the strainfield, which can be regarded as composed of multiple-signals of specific spatial

682   range and structural significance.

683   - Revealing contrasted mechanical behaviors of lithological/structural domains. Indeed,

684   results show that spatial strain gradients of structural domains can be evaluated from the

685   trend of the corresponding variogram functions. Geostatistical analysis thus allows

686   distinguishing pervasive *vs.* localized deformation regimes at a given scale. Besides, the

687   original variogram trend can also point-out a role of late structures (faults in particular)

688   forming discontinuities and perturbations in the paleo-strainfield.

902   **Figure captions**

903   Figure 1: a) Sketch map of the Paleozoic crust of the Pyrenees. The plutons and gneiss domes

904   cited in the text are located. Location of the two cross-sections of Figs. 1b & 1c and Fig. 2 are

905   also shown. Abbreviation for west to east: Ct: Cauterets pluton, CL: Chiroulet-Lesponne dome,

906   Nv: Néouvielle pluton, LC: Lys-Caillaouas dome, Bo: Bossost dome, Ma: Maladeta pluton, Ba:

907   Bassiès pluton, As: Aston gneiss dome, Ho: Hospitalet gneiss dome, ML: Mt Louis pluton, Qt:

908   Quérigut pluton, Mi: Millas pluton, Ca: Canigou gneiss dome, Ab: Albères gneiss dome. In dark-

909   grey: main Variscan shear zones; in blue: main Alpine faults; b) Simplified cross-section from

910   the central Axial Zone, modified from Cochelin et al., 2018; c) simplified cross-section from the

911   eastern Pyrenees, modified from Cochelin et al., 2017

912   Figure 2: Simplified geological map of the Canigou gneiss dome, modified from Guitard et al.,

913   (1992) Carreras et al., (2004); Baudin et al., (2008); Donzeau et al., (2010).

914   Figure 3: Summary of the following steps to compute foliation trajectories. See in the text for

915   further explanation.

916   Figure 4: Summary of the following steps to compute lineation trajectories, using lineation data

917   set presented in Fig. 3.

918   Figure 5: a) Histogram of cleavage directional data, b) histogram of cleavage directional data in

919   the upper crust; c) histogram of foliation directional data in the middle crust. The calculated

920   skewness for each histogram corresponds to the nonparametric skew. Rose diagrams of dip

921   values of cleavage/foliation planes in the Axial Zone (d), the middle crust (e) and the upper crust

922   (f).

923   Figure 6: a) Omni-directional variograms computed for schistosity directional data, with the

924   omni-directional variograms computed for the whole Axial Zone in black, the upper crust in blue

925 and the mid-lower crust in red. Dots represent the experimental variograms and full lines are the

926 fest-fit functions; b) Omni-directional variograms of dip values for the Axial Zone (black) and

927 the upper crust (blue).

928 Figure 7: a) Cleavage trend trajectories computed from the interpolated cleavage direction in the

929 whole Axial Zone, taking into account gneiss domes and plutons; b) R map computed from the

930 interpolated cleavage direction. High dispersion is highlighted by low R values in orange and red.

931 Figure 8: a) Interpolated dip of cleavage in the Axial Zone. Gneiss domes are located in red and

932 plutons in black. b) Computed slope of dip values in the Axial Zone. Sharp variations are

933 highlighted by high slopes in red (0.83 to 2.26%) and beige (0.45-0.82%).

934 Figure 9: Directional variograms computed in the upper crust: a) for azimuth of cleavage along

935 the N45° direction in the upper crust; b) for azimuth of cleavage along EW, NW-SE and NS

936 directions in the upper crust. c) N100° directed variogram computed for dip values in the upper

937 crust. d) N10° directed variogram computed for dip values in the upper crust.

938 Figure 10: a) Cleavage trend trajectories computed from the interpolated cleavage direction in the

939 upper crust; b) Interpolated dip of cleavage in the upper crust. These interpolations were obtained

940 using nugget effect and ranges deduced from the variogram analysis of the upper crust (Fig.6a).

941 Figure 11: Ternary diagrams (Pitch-Plunge-Dip) illustrating the crustal flow mode in orogens,

942 after Chardon et al., (2009) for mineral-stretching lineations in the upper crust (left) and the mid-

943 lower crust (right) of the Variscan Pyrenees. Because the association of foliation and lineation in

944 each station was not possible for digitalized data, those presented in this figure come from our

945 own measurement (see Cochelin et al., 2017).

946   Figure 12: a) Omni-directional variogram computed for directional data in the Mt Louis pluton;

947   b) Zoom on the regional trajectories obtained around the Mt Louis pluton (Fig. 7a); c) Foliation

948   trajectories obtained using parameters deduced from the omni-directional variogram of the

949   pluton; d) Foliation trajectories obtained manually by Bouchez and Gleizes (1995) on the basis of

950   ASM measurement and field observations.

951   Figure 13: Zoom on the Canigou gneiss dome. a) Omni-directional variogram calculated for

952   foliation planes within the gneiss dome; b) Local foliation trajectories in the Canigou gneiss

953   dome (in red); Trajectories around the gneiss dome (in grey) are from the regional interpolation

954   (Fig. 7a). c) Location of high dispersion of directional data in the Canigou gneiss dome

955   combining of zoom of the R map (Fig. 7b), local trajectories (Fig. 13b) and location of the main

956   fault zones (Fig. 2).

957   Figure 14: a) Stereogram of mineral-stretching lineations in the Canigou gneiss dome; b) Omni-

958   directional variogram computed for stretching lineations; c) Computed lineation trajectories in

959   the Canigou gneiss dome.

960   Figure 15: a) Synthesis of direction of stretching within gneiss domes in the Axial Zone,

961   modified from Cochelin et al., 2017; b) Rose diagram of mineral-stretching lineations set

962   available for gneiss domes

963   Figure 16: Bloc diagram summarizing how strain was spatially partitioned in the Axial Zone,

964   showing: the steep longitudinal cleavage trajectories in the upper crust (1) and associated

965   transpressional shear zones in blue surrounding syn-kinematic plutons (2) and gneiss domes (3)

966   affected by longitudinal stretching. The simplified trend of variograms for each structural features

967   is presented: the nested variogram of the Axial Zone, summing the individual variograms of (1)

41

968   the upper crust with its exponential trend; (2) syntectonic plutons showing sinusoidal trend; (3)

969   gneiss domes which could have a sinusoidal trend (i.e. single phased or "undisturbed" domes) or
970   an exponential trend (i.e. polyphased domes like the Canigou).

Highlights

- Spatial orientation variability of schistosity planes is quantified by variograms

- Building of quantitative regional and local strainfields using kriging interpolations

- The analysis of fabrics and kinematic data documents strain partitioning patterns

- Variogram analysis allows deciphering continuous from polyphased deformation
