ABSTRACT

We investigate under which conditions supermassive hot Jupiters can sustain source regions for radio emission, and whether this emission could propagate to an observer outside the system. We study Tau Bootis b-like planets (a supermassive hot Jupiter with 5.84 Jupiter masses and 1.06 Jupiter radii), but located at different orbital distances (between its actual orbit of 0.046 and 0.2 au). Due to the strong gravity of such planets and efficient radiative cooling, the upper atmosphere is (almost) hydrostatic and the exobase remains very close to the planet, which makes it a good candidate for radio observations. We expect similar conditions as for Jupiter, i.e. a region between the exobase and the magnetopause that is filled with a depleted plasma density compared with cases where the whole magnetosphere cavity is filled with hydrodynamically outward flowing ionospheric plasma. Thus, unlike classical hot Jupiters like the previously studied planets HD 209458b and HD 189733b, supermassive hot Jupiters should be in general better targets for radio observations.

Key words: planets and satellites: atmospheres – planets and satellites: aurorae – planets and satellites: detection – planets and satellites: magnetic fields – planet-star interactions – radio continuum: planetary systems.

1 INTRODUCTION

It is known that the solar system planets emit low-frequency, coherent, polarized radio emission (e.g. Zarka 1998; Farrell, Desch & Zarka 1999; Ergun et al. 2000; Treumann 2006), where electric fields parallel to the magnetic field accelerate electrons towards the planet into a region of increasing magnetic field. The electrons are partially reflected upwards and some are lost to the planetary atmosphere. The reflected electrons exhibit an unstable distribution, e.g. a loss cone or a horseshoe distribution (e.g. Treumann 2006). The process leading to (exo)planetary radio emission from this electron distribution is the CMI (cyclotron maser instability). It works

only if the local electron plasma frequency is smaller than the local electron cyclotron frequency, $\omega_p < \omega_c$. In particular, it works most efficiently if $\omega_p \ll \omega_c$. Thus, the strongest radio emission comes from regions of low plasma density and strong magnetic field.

It is natural to assume that this process is also operating for planets outside the solar system. Various observation campaigns and theoretical studies investigated the possible radio emission from extrasolar planets (see Weber et al. 2017a, and references therein). Here, we only highlight two recent theoretical studies by Grießmeier (2017) and Lynch et al. (2018). They extended the studies on detectability of exoplanetary radio emission by Lazio et al. (2004), Grießmeier, Zarka & Spreeuw (2007b), and Grießmeier, Zarka & Girard (2011) to the exoplanet census at the time of their respective studies. Lynch et al. (2018) predict the planets V830 Tau b, BD+20 1790 b, and GJ 876 b to generate observable levels of radio emis-

* E-mail: chris210007@hotmail.com (CW); nerkaev@gmail.com (NVE); Helmut.Lammer@oeaw.ac.at (HL);

sion. Grießmeier (2017) find, e.g. Eps Eridani b and Tau Bootis b to be good candidates.

While close-in hot Jupiters have long been considered favourable candidates for observing radio emission, it has recently been pointed out by Weber et al. (2017a, 2017b) and Daley-Yates & Stevens (2017, 2018) that close-in planets can have hydrodynamically expanded upper atmospheres and ionospheres due to the strong stellar XUV (X-ray and extreme ultraviolet) irradiation. These ionospheres can be very dense, leading to a high local plasma frequency. In some cases, this can lead to quenching of the planetary radio emission in the sense that either no emission can be generated, or that the emission is absorbed in the planetary ionosphere, which extends up to the magnetopause. For a planet of Jupiter’s mass or less, one way to prevent this effect would be to look at planets at a larger distance from the star. This, however, weakens the interaction between the star and the planet and the energy input into the planetary magnetosphere, which is usually assumed to be essential for the generation of intense radio emission [a few alternative models do not rely on the proximity of the planet to the host star, see e.g. Grießmeier (2017) for a comparison]. Another way to avoid planets with hydrodynamically extended atmospheres and ionospheres would be to study planets around stars with a weaker XUV flux, like the massive A5 star WASP-33 which hosts a hot Jupiter orbiting at a distance of 0.02 au (e.g. Herrero et al. 2011), or massive gas giants with several Jupiter-masses where the gravity may act against hydrodynamic expansion of their upper atmospheres.

Recently, Hallinan et al. (2015) detected aurorae from a brown dwarf. Since brown dwarfs are very massive their atmospheres should be very compact and they should not have an extended upper atmosphere and ionosphere, but rather a magnetosphere with vast regions of depleted plasma. Thus, they should exhibit source regions where the detected emission is produced and radio waves can freely propagate to an observer on, e.g. Earth. Such kind of objects belong to the so-called ultra-cool dwarfs and they form a bridge between hot Jupiters and stars (Route & Wolszczan 2016b; Llama et al. 2018). Hallinan et al. (2008) confirmed that these dwarf stars can have strong dynamos leading to magnetic fields strong enough to generate radio emission via the electron CMI (e.g. Treumann 2006). The authors observed an M-dwarf and an L-dwarf, detecting 100 per cent circularly polarized and coherent radio emission requiring magnetic fields in the kG-range. These observations confirmed the CMI to be the dominant mechanism for the generation of radio emission in magnetospheres of ultra-cool dwarfs (Hallinan et al. 2008). Several other authors reported successful observations (Berger et al. 2010; Williams, Berger & Zauderer 2013; Route & Wolszczan 2016a,b; Williams, Gizis & Berger 2017).

Since radio emission from ultra-cool dwarfs has been already detected and they bridge stars with hot Jupiters, it seems natural to investigate if supermassive hot Jupiters provide better conditions for the CMI than the classical hot Jupiters studied in Weber et al. (2017a). Thus, in this work we are investigating the possible generation of radio emission from Tau Bootis b and the propagation of radio waves in the planetary vicinity. Since the first theoretical studies of exoplanetary radio emission, this planet has frequently been considered as one of the best candidates for radio observations (e.g. Farrell et al. 1999; Grießmeier et al. 2005; Grießmeier et al. 2006a; Grießmeier et al. 2007a,b, 2011; Reiners & Christensen 2010; Grießmeier 2017). It has been the target of a number of radio observational campaigns (e.g. Bastian, Dulk & Leblanc 2000; Farrell et al. 2003; Lazio et al. 2004; Ryabov, Zarka & Ryabov 2004; Majid et al. 2006; Shiratori et al. 2006; Winterhalter et al. 2006; Lazio & Farrell 2007; Stroe, Snellen & Röttgering 2012; Hallinan

et al. 2013), and more observations of this planet have recently been performed with LOFAR (e.g. Turner et al. 2017).

Here, Tau Bootis b will serve as the archetype of a certain class of planets, i.e. supermassive hot Jupiters. The planet has a minimum mass ($M \sin i$) of 4.13 Jupiter masses, with an estimated true mass of 5.84 Jupiter masses (www.exoplanet.eu, accessed June 2018). There are currently 92 known exoplanets with more than two Jupiter masses and orbital distances of less than 0.1 au.

Twelve of these planets are located at distances ≤ 100 pc from Earth. Supermassive hot Jupiters like Tau Bootis b may constitute some of the most promising candidates for radio observations. First, they are likely to have strong magnetic fields. In fact, all magnetic field estimations indicate that massive, gaseous planets should have stronger magnetic fields than less massive Jupiter-like gas giants (Grießmeier et al. 2004; Reiners & Christensen 2010). This increases the chance to generate radio emission with frequencies above the Earth’s ionospheric cutoff of 10 MHz and increases the power that can be received by wide-band radio observations. Secondly, their high masses (and thus larger gravity) lead to more compact upper atmospheres.

For planets more massive than Jupiter, like Tau Bootis b, the planetary gravity keeps the atmosphere strongly bound. In some cases, this will lead to a hydrostatic rather than hydrodynamic upper atmosphere (for example, WASP-18b, is one of these cases; Fossati et al. 2018), so that radio emission could be generated and may escape, a situation which is comparable with the known solar system conditions, e.g. Earth. In other words, a more massive planet maintains hydrostatic conditions closer to its host star than less massive, Jupiter-like planets. This has an added benefit for observational campaigns: close-in planets are easier to study from an observer’s point of view, as it is easier to cover one full planetary orbit. In fact, the planetary radio emission is assumed to vary with the planetary orbit, which is one of the ways to discriminate between stellar and planetary emission (see e.g. Grießmeier et al. 2005). The variation is caused by the inhomogeneity of both the planetary magnetic field and the stellar wind (and its magnetic field). For this reason, the stellar rotation has also to be taken into account (Fares et al. 2010), which is particularly important if the stellar rotation and the planetary orbital motion are tidally synchronized (which seems to be the case for Tau Bootis; Donati et al. 2008). Whether the gravity is indeed strong enough to prevent the quenching of planetary radio emission has to be studied on a case-by-case basis; in this follow-up study to Weber et al. (2017a), we investigate the case of Tau Bootis b.

Section 2.1 describes briefly the upper atmosphere model used for evaluating the electron density profiles shown in Section 3 and shows the planetary and stellar parameters. This section also describes the upper atmosphere structure of Tau Bootis b at different orbit locations. The estimation of the magnetopause standoff distance as well as the stellar wind parameters are shown in Section 2.2. This section also shows a comparison of standoff distance and exobase level. Section 3 addresses the results for the plasma environment and the corresponding plasma and cyclotron frequencies. Section 4 shortly addresses the implications of our study for future radio observations of Tau Bootis b. Section 5 presents our conclusions.

2 MODEL DESCRIPTION

2.1 Upper atmosphere modelling

In Weber et al. (2017a), we used upper atmosphere profiles from hydrodynamic models which include heating by stellar XUV ra-

diation, ionization, and dissociation of hydrogen. This is a valid approach for most hot Jupiters which have expanded and efficiently escaping atmospheres.

In cases of extremely massive planets, an upper atmosphere in the hydrodynamic regime is hardly possible, and thus it is reasonable to apply equilibrium equations for the atmospheric parameters. We derive these equations from the hydrodynamic system in Erkaev et al. (2016) by neglecting terms with time derivatives and bulk velocities. The equations for pressure P and temperature T are as follows :

$$\frac{\partial P}{\partial R} = -\rho \frac{\partial U}{\partial R}, \quad (1)$$

$$Q_{\text{EUV}} - Q_{\text{cool}} + \frac{\partial}{R^2 \partial R} \left(R^2 \chi \frac{\partial T}{\partial R} \right) = 0. \quad (2)$$

Here, R is the distance from the planet, U is the gravitational potential, χ is the thermal conductivity of the atmosphere (Watson, Donahue & Walker 1981), given by

$$\chi = 4.45 \times 10^4 \left(\frac{T}{1000 \text{ K}} \right)^{0.7}, \quad (3)$$

Q_{EUV} is the stellar EUV (extreme ultraviolet) volume heating rate

$$Q_{\text{EUV}} = \eta \sigma_{\text{EUV}} (n_{\text{H}} + n_{\text{H}_2}) \phi_{\text{EUV}}, \quad (4)$$

η is the ratio of the net local heating rate to the rate of the stellar radiative absorption in the planetary atmosphere (assumed to be 15 per cent, in agreement with Shematovich, Ionov & Lammer 2014) and Q_{cool} is the cooling rate. The latter consists of the Lyman- α ($Q_{\text{L}\alpha}$),

$$Q_{\text{L}\alpha} = 7.5 \times 10^{-19} n_{\text{e}} n_{\text{H}} \exp(-118348 \text{ K}/T), \quad (5)$$

the H collision ionization (Q_{ci}), Bremsstrahlung (Q_{BS}), and H_+ radiative recombination (Q_{rec}) cooling processes, i.e. $Q_{\text{cool}} = Q_{\text{L}\alpha} + Q_{\text{ci}} + Q_{\text{BS}} + Q_{\text{rec}}$. The quantity σ_{EUV} is the cross-section of EUV absorption.

The cooling rates Q_{ci} , Q_{BS} , and Q_{rec} are taken from Glover & Jappsen (2007). ϕ_{EUV} is the function describing the EUV flux absorption in the atmosphere

$$\phi_{\text{EUV}} = \frac{1}{2} \int_0^{\pi/2 + \arccos(1/r)} J_{\text{EUV}}(r, \theta) \sin(\theta) d\theta. \quad (6)$$

Here, $J_{\text{EUV}}(r, \theta)$ is a function of spherical coordinates that describes the spatial variation of the EUV flux due to the atmospheric absorption (Erkaev et al. 2015), r corresponds to the radial distance from the planetary centre normalized to the planetary photospheric radius R_0 .

The mass density, ρ , and the pressure, P , are related to the species densities as follows:

$$\rho = m_{\text{H}} (n_{\text{H}} + n_{\text{H}^+}) + m_{\text{H}_2} (n_{\text{H}_2} + n_{\text{H}_2^+}), \quad (7)$$

$$P = (n_{\text{H}} + n_{\text{H}^+} + n_{\text{H}_2} + n_{\text{H}_2^+} + n_{\text{e}}) kT, \quad (8)$$

where k is the Boltzmann constant, and m_{H} and m_{H_2} are the masses of the hydrogen atoms and molecules, respectively.

Steady-state densities of atomic and molecular hydrogen, ions, and electrons satisfy the following algebraic equations:

$$\nu_{\text{H}} n_{\text{H}} + \nu_{\text{Hcol}} n_{\text{e}} n_{\text{H}} - \alpha_{\text{H}} n_{\text{e}} n_{\text{H}^+} = 0, \quad (9)$$

$$- \nu_{\text{H}_2} n_{\text{H}_2} - \nu_{\text{dis}} n_{\text{H}_2} n + \gamma_{\text{H}} n n_{\text{H}^+}^2 = 0, \quad (10)$$

Table 1. Tau Bootis system parameters. The stellar and planetary parameters are from http://exoplanet.eu/catalog/tau_boo_b/, accessed on June 2018.

Table 2. Stellar XUV radiation at different orbital separations for Tau Bootis. Planetary atmospheric temperature and pressure P_0 of a Tau Bootis b-like planet at different orbital distances.

Orbital distance (au)	XUV (W m^{-2})	Temperature T_0 (K)	Pressure P_0 (mbar)
0.046	17.53	1700	100
0.1	3.71	1150	100
0.2	0.93	810	100

$$\nu_{\text{H}_2} n_{\text{H}_2} - \alpha_{\text{H}_2} n_{\text{e}} n_{\text{H}_2^+} = 0. \quad (11)$$

The electron density is determined by the quasi-neutrality condition

$$n_{\text{e}} = n_{\text{H}^+} + n_{\text{H}_2^+} \quad (12)$$

and the total hydrogen number density is a sum of the partial densities

$$n = n_{\text{H}} + n_{\text{H}^+} + n_{\text{H}_2} + n_{\text{H}_2^+}. \quad (13)$$

The term α_{H} is the recombination rate related to the reaction $\text{H}^+ + e \rightarrow \text{H}$ of $4 \times 10^{-12} (300 \text{ K}/T)^{0.64} \text{ cm}^3 \text{ s}^{-1}$, α_{H_2} is the dissociation rate of $\text{H}_2^+ + e \rightarrow \text{H} + \text{H}$: $\alpha_{\text{H}_2} = 2.3 \times 10^{-8} (300 \text{ K}/T)^{0.4} \text{ cm}^3 \text{ s}^{-1}$, ν_{dis} is the thermal dissociation rate of $\text{H}_2 \rightarrow \text{H} + \text{H}$: $1.5 \times 10^{-9} \exp(-49000 \text{ K}/T)$, γ_{H} is the rate of the reaction $\text{H} + \text{H} \rightarrow \text{H}_2$: $\gamma_{\text{H}} = 8.0 \times 10^{-33} (300 \text{ K}/T)^{0.6}$ (Yelle 2004).

The term ν_{H} is the hydrogen ionization rate, and ν_{H_2} is the ionization rate of molecular hydrogen (Storey & Hummer 1995; Murray-Clay, Chiang & Murray 2009),

$$\nu_{\text{H}} = 5.9 \times 10^{-8} \phi_{\text{EUV}} \nu_{\text{S}}^{-1}, \quad \nu_{\text{H}_2} = 3.3 \times 10^{-8} \phi_{\text{EUV}} \nu_{\text{S}}^{-1}, \quad (14)$$

and ν_{Hcol} is the collisional ionization rate (Black 1981), $\nu_{\text{Hcol}} = 5.9 \times 10^{-11} T^{1/2} \exp(-157809 \text{ K}/T)$.

It turns out that the H_2^+ density is much smaller than that of other species. This allows us to neglect $n_{\text{H}_2^+}$ in the equations for the electron and total densities (equations 12 and 13). With this assumption, we solve the equations (9)–(13) and express the total, molecular, ion, and electron densities through one quantity – the atomic hydrogen density. Substituting these expressions to (8) and (7), we solve finally two ordinary differential equations (1) and (2).

Table 1 summarizes the Tau Bootis b system parameters. Table 2 shows the XUV fluxes at orbital distances of 0.046, 0.1, and 0.2 au from Tau Bootis as well as the temperature T_0 and pressure P_0 at the photosphere.

The lower boundary is set at the planetary photospheric radius R_0 . For all cases, and throughout this study, we consider that R_0 lies at an atmospheric pressure P_0 of about 100 mbar. This is justified by the fact that, for an H_2 -dominated atmosphere considering a clear atmosphere and taking into account H_2 Rayleigh scattering, H_2 - H_2 collisional-induced absorption, alkali lines, and solar-abundance molecular bands, the optical depth at visible wavelengths is unity at a pressure level of about 100 mbar (Cubillos 2016; Lammer et al. 2016; Cubillos et al. 2017; Fossati et al. 2017). The atmospheric temperature T_0 at R_0 is assumed to be the equilibrium temperature at the planet's orbital location (see Table 2).

To infer the XUV flux of Tau Bootis, we have first derived the chromospheric emission at the core of the Ca II H&K lines, for which high-quality observations are available, and converted it to an XUV flux value. We have first computed the synthetic spectral energy distribution of the stellar photosphere employing the LLMODELS stellar model atmosphere code (Shulyak et al. 2004) to which we have then added various levels of emission at the core of the Ca II H&K lines, as described in Fossati et al. (2015), until we could fit the optical observations obtained with the ESPADONS spectropolarimeter available in the CFHT archive. The star Tau Bootis is located much closer than 100 pc, thus interstellar medium absorption does not significantly affect the Ca II line core emission (Fossati et al. 2017). In this way, we obtained an integrated Ca II chromospheric emission flux at a distance of 1 au from the star of 0.05 W m^{-2} . We have converted this flux into a Ly α flux and then into an XUV flux using the scaling relations of Linsky, France & Ayres (2013); Linsky, Fontenla & France (2014), obtaining an XUV flux of 17.5 W m^{-2} at the distance of the planet. Being based on two scaling relations, this value has an uncertainty of the order of 50 per cent (e.g. Fossati et al. 2015).

Fig. 1 shows the number density profiles of H, H_2 , H^+ , and H_2^+ (i.e. neutrals and plasma) at 0.046, 0.1, and 0.2 au for Tau Bootis b (upper panels and lower left panel) and the temperature profile for the different orbital distances (right lower panel). The temperature peak for Tau Bootis b that would be needed for hydrodynamic escape is about $\sim 100\,000\text{K}$, i.e. one order of magnitude higher than for the previously studied hot Jupiter HD 209458b. Such a high temperature is not realistic, because cooling processes can reduce it immediately. In case of a supermassive planet, the temperature peak is so high that the cooling processes make a significant contribution. Therefore, the cooling processes reduce the temperature peak below the critical level needed for a hydrodynamic escape regime. When trying to run a hydrodynamic code with cooling for the case of a supermassive planet, there is no radial acceleration of the atmospheric particles because the temperature is not sufficiently high for such acceleration against the gravitational forces. We plan to investigate this effect in detail within a follow-up study. The atmosphere is not expanding hydrodynamically and very favourable conditions for the CMI can be expected. The strong gravity and the radiative cooling keep the atmosphere compact, and we expect similar conditions as, e.g. Jupiter, with large regions of depleted plasma between the exobase and the magnetopause.

By estimating the hydrogen scale height ($H = kT_{\text{exo}}/m_{\text{H}}g$, where k is the Boltzmann constant, T_{exo} the temperature at the exobase, m_{H} the hydrogen mass, and g the gravitational acceleration) at the exobase level of Tau Bootis b and Jupiter we obtain 4443 and 365 km, respectively. The distance between the exobase and the magnetopause for Jupiter is $40.9 R_{\text{J}}$ or 7.8×10^3 scale heights and $3.6 R_{\text{p}}$ or about 60 scale heights for Tau Bootis b. One can expect that the exosphere density of Tau Bootis b decreases fast so that the plasmasphere between the exobase and possible magnetopause dis-

tances will be populated mainly with stellar wind plasma. Of course the stellar wind plasma at the orbit of Tau Bootis b is much higher than at 5.2 au but this poses no problem for the propagation of possibly generated radio waves (Grießmeier et al. 2007b). Therefore, the upper atmosphere-magnetosphere configuration and the related plasmasphere are more comparable with Jupiter's environment in the Solar System, making the production of radio waves by the CMI and propagation in that environment more likely compared to classical hot Jupiters like HD 209458b or HD 189733b.

2.2 Comparison between exobase and magnetopause standoff distance

The magnetopause standoff distances are calculated from (e.g. Grießmeier et al. 2004; Khodachenko et al. 2012; Kislyakova et al. 2014)

$$R_s = \left(\frac{\mathcal{M}^2 \mu_0 f_0^2}{8\pi^2 \rho_{\text{sw}} v_{\text{sw}}^2} \right)^{\frac{1}{6}}. \quad (15)$$

Here, μ_0 is the vacuum permeability and $f_0 = 1.22$ is a form factor for the magnetopause shape including the influence of a magnetodisk (Khodachenko et al. 2012). v_{sw} is the stellar wind velocity corrected for the orbital motion of the planet. ρ_{sw} is the stellar wind density, and \mathcal{M} is the magnetic moment. Table 3 summarizes the stellar wind parameters from the model of Grießmeier et al. (2007a,b) for the different orbital distances.

Fig. 2 shows the exobase levels R_e compared to the magnetopause standoff distances R_s as a function of orbital distance for the magnetic moments as predicted by Grießmeier et al. (2007a) for Tau Bootis b and the planets studied in Weber et al. (2017a), i.e. HD 209458b and HD 189733b. For Tau Bootis b, the exobase is very close to the planet (at 1.18, 1.14, and 1.11 R_{p} for 0.046, 0.1, and 0.2 au, respectively) and the magnetospheric cavity for the CMI to work can be expected to be very large. For all orbital distances between 0.046 and 0.2 au the exobase is smaller than the standoff distance. For HD 209458b and HD 189733b, assuming the same XUV flux as for Tau Bootis b, for each of the investigated orbits the exobase is larger than the magnetopause standoff distance.

3 PLASMA ENVIRONMENT AND CORRESPONDING FREQUENCIES

For the cyclotron frequency, we test three different hypotheses for the planetary magnetic moment: (a) we use the magnetic field strengths predicted by Grießmeier et al. (2007a), (b) we compare to the value of Reiners & Christensen (2010), and (c) we also compare to results using the rotation-independent value of Grießmeier et al. (2011). To calculate the corresponding cyclotron frequency f_c , we use

$$f_c = \frac{1}{2\pi} \frac{e \cdot B}{m_e}. \quad (16)$$

Here, e is the electron charge, B the magnetic field strength, and m_e the electron mass. The relation between magnetic dipole moment and the maximum magnetic field strength at the pole is given by

$$B = \frac{\mu_0 \mathcal{M}}{4\pi R_{\text{p}}^3}, \quad (17)$$

Figure 1. Top panels and bottom left panel: H, H₂, H⁺, and H₂⁺ densities at orbital distances of 0.046, 0.1, and 0.2 au for Tau Bootis b around the F7V star Tau Bootis. Note that we only plot the regions up to the exobase level. Bottom right panel: temperature profiles for 0.046, 0.1, and 0.2 au.

Table 3. Stellar wind parameters (velocity v_{sw} and density n_{sw}) of Tau Bootis at different orbital distances.

Orbital distance (au)	v_{sw} (km s ⁻¹)	n_{sw} (m ⁻³)
0.046	272	4.16×10^{10}
0.1	340	6.04×10^9
0.2	408	1.22×10^9

where R_p is the planetary radius, μ_0 is the vacuum permeability, and \mathcal{M} is the magnetic moment. The plasma frequency is calculated via

$$f_p = \frac{1}{2\pi} \sqrt{\frac{e^2 n_e}{m_e \epsilon_0}}, \quad (18)$$

with n_e the electron density and ϵ_0 the vacuum permittivity. For the electron density at Tau Bootis b, results from Section 2.1 are evaluated.

The plasma and cyclotron frequency are calculated to check whether the condition for the CMI to work (i.e. $f_p \ll f_c$) is fulfilled (Weber et al. 2017a, 2017b).

Grieffmeier et al. (2007a) predicted the magnetic moment of Tau Bootis b to be $0.76 M_J$, where M_J is the Jovian magnetic moment. For the magnetic moment, we also considered the model by Reiners & Christensen (2010), in which tidal locking has no influence. They predict a dipole magnetic field strength at the pole of 58 G. This corresponds to a magnetic moment of $1.25 \times 10^{28} \text{ Am}^2 \approx 7.5 M_J$. The value found in Grieffmeier et al. (2011) corresponds to $\approx 20.3 \text{ G}$ and a magnetic moment of $2.8 M_J$.

A recent study by Yadav & Thorngren (2017) states that magnetic moments of up to 10 times stronger than those of Jupiter can be expected for hot Jupiters regardless of their age, provided that the energy of the stellar radiation is deposited in the planetary centre. With the processes suggested here this is, however, not a realistic assumption. In the more realistic case of energy deposition in the planet's outer layers, the extra energy would reduce the thermal gradient within the planet or even invert it. This would reduce the convection in the planet. Rather than strengthening the plane-

Figure 2. Exobase levels R_e compared to the magnetopause standoff distances R_s as a function of orbital distance for the magnetic moments as predicted by Grieffmeier et al. (2007a) for Tau Bootis b and the planets studied in Weber et al. (2017a).

Figure 3. Electron density profiles of a Tau Bootis b-like planet at orbital distances of 0.046 (red), 0.1 (green), and 0.2 au (magenta). The curves end at the exobase level.

Figure 4. Comparison of cyclotron frequency to plasma frequency. The red, green, and magenta lines correspond to the plasma frequency at 0.046, 0.1, and 0.2 au, respectively, and stop at the exobase levels. The dashed green line shows the cyclotron frequency corresponding to a magnetic moment as predicted by Grießmeier et al. (2007a). The dashed blue line shows the cyclotron frequency corresponding to a polar magnetic field strength of 58 G, as predicted by Reiners & Christensen (2010). The dashed magenta line corresponds to the prediction by Grießmeier et al. (2011). The solid and dashed cyan lines correspond to the plasma and cyclotron frequencies at Jupiter, respectively. The plotting range stops at the largest exobase level (1.18 R_p at 0.046 au).

tary dynamo, this would weaken it, and could even shut it down altogether.

Fig. 3 shows the electron density profiles of Tau Bootis b placed at 0.046 au (red line), 0.1 au (green line) and 0.2 au (magenta line). Fig. 4 shows the cyclotron frequency (green, blue, and magenta dashed lines) and the plasma frequency at different orbital distances (red, green, and magenta lines). The cyclotron frequency was calculated from equation (16) assuming a dipolar magnetic field, using the predicted magnetic moments of $0.76 \mathcal{M}_J$ from Grießmeier et al. (2007a; dashed green line, denoted by G2007), the predicted 58 G ($7.5 \mathcal{M}_J$) from Reiners & Christensen (2010; dashed blue line, denoted by RC2010) and the value of $2.8 \mathcal{M}_J$ found in Grießmeier et al. (2011; dashed magenta line, denoted by G2011). Radio emission is generated at frequencies close to the local cyclotron frequency

of the electrons. Only if the cyclotron frequency exceeds the local plasma frequency ($f_p/f_c \leq 0.4$; Grießmeier et al. 2007a), the condition for the generation of radio waves is fulfilled and radio waves with a frequency $f_c > f_p$ can be generated. Radio waves generated at a hypothetical distance R_1 can escape from their generation region through the planetary atmosphere/ionosphere if and only if the cyclotron frequency at the distance R_1 is higher than the plasma frequency for all distances $R_1 < R < \infty$.

All curves in Fig. 4 stop at the exobase level. The range of the plot stops at the exobase level for 0.046 au, i.e. 1.18 R_p . In the regions up to the exobase level for the magnetic field cases RC2010 and G2011 possibly generated radio waves can escape but not for G2007. However, the exobase levels are very low, i.e. 1.18, 1.14, and 1.11 R_p for 0.046, 0.1, and 0.2 au, respectively. This means that the atmosphere is very compact. Beyond the exobase the conditions for the CMI are very likely much better. Thus, each magnetic field case should yield the possibility of generation and escape for radio emission. Only for the case G2007 emission generated in the small region below the exobase levels would not be able to escape. Beyond the exobase, all cyclotron frequencies should exceed the plasma frequencies.

Fig. 5 shows the ratios of plasma to cyclotron frequency for the orbits 0.046, 0.1, and 0.2 au, respectively. For each orbit the corresponding plasma frequency is compared with the different cyclotron frequencies corresponding to the magnetic field cases as discussed above, i.e. the case G2007, corresponding to the magnetic moment as predicted by Grießmeier et al. (2007a), the case RC2010, corresponding to the magnetic moment as predicted by Reiners & Christensen (2010) and the case G2011, corresponding to the magnetic moment as predicted by Grießmeier et al. (2011). The solid black line indicates the maximum frequency ratio of 0.4 for the CMI to work (see Grießmeier et al. 2007b; Weber et al. 2017a). The same argument as above holds, i.e. because the plotting range stops at the exobase levels, the conditions for the CMI in these small region are not good only for the case G2007. Beyond the exobase, for every magnetic field case, the plasma frequency should be below the cyclotron frequency almost everywhere within the magnetosphere. This can be seen very well by the decreasing trend of the frequency ratios for all cases. When there is no hydrodynamic atmospheric outflow then exobase densities are always similar. Thus, we can expect a situation comparable to Jupiter in the solar system at 5.2 au, where the frequency ratios are well below the indicated maximum of 0.4 because the plasma density decreases very fast beyond the exobase level. For details on the Jovian plasma environment, we refer to, e.g. Prasad & Capone (1971), Machida & Nishida (1978), Luhmann & Walker (1980), Yelle et al. (1996), Stallard et al. (2001).

Table 4 gives a summary of the possibility for generation and escape of potential radio emission for the cases studied in this paper. The + signs indicate that generation or escape is possible. The case of Jupiter (1 M_J) is intended as comparison to the cases studied here. To compare the results of the current study with our former findings, Table 5 shows the same summary as for Tau Bootis b, but for the planets HD 189733b and HD 209458b from Weber et al. (2017a). In the version of the table used here we filled the gaps in the table of Weber et al. (2017a). The question marks in the last column indicate that it is not sure if the radio emission actually cannot escape and if it is really only generated very close or maybe also at larger distances from the planet’s surface. For details on the case of HD 209458b at 1 au we refer to Weber et al. (2017a).

Figure 5. Ratio of plasma to cyclotron frequency for Tau Bootis b for different orbital distances. Upper left panel: 0.046 au. Upper right panel: 0.1 au. Lower panel: 0.2 au. The black solid line indicates the maximum ratio of 0.4 for the CMI to work. Note that the curves end at the exobase levels.

Table 4. Summary of possibility for generation and escape of radio emission for the case studied in this paper. The case of Jupiter with $1 M_J$ is shown for comparison. The numbers in brackets are the maximum emission frequencies in MHz at the pole.

Magnetic moment (\mathcal{M}_J)	0.046 au	0.1 au	0.2 au
	Tau Bootis		
$0.76 \mathcal{M}_J$ ($\hat{=} 16.3$ MHz, G2007)	Generation: + Escape: +	Generation: + Escape: +	Generation: + Escape: +
$1 \mathcal{M}_J$ ($\hat{=} 21.5$ MHz)	Generation: + Escape: +	Generation: + Escape: +	Generation: + Escape: +
$2.8 \mathcal{M}_J$ ($\hat{=} 60$ MHz, G2011)	Generation: + Escape: +	Generation: + Escape: +	Generation: + Escape: +
$7.5 \mathcal{M}_J$ ($\hat{=} 161$ MHz, RC2010)	Generation: + Escape: +	Generation: + Escape: +	Generation: + Escape: +

4 IMPLICATIONS FOR FUTURE OBSERVATION CAMPAIGNS TARGETING TAU BOOTIS B

Radio emission from the Tau Bootis b system has not been detected yet, even though we find, in agreement with several former studies (e.g. Farrell et al. 2003; Grießmeier et al. 2005, 2006b; Grießmeier 2007; Grießmeier et al. 2007b,a; Lazio & Farrell 2007; Grießmeier et al. 2011), that it should be a good candidate for successful observations. Radio fluxes were predicted to be in the sensitivity range of several radio telescopes, e.g. UTR-2 and LOFAR. Grießmeier et al. (2011) compared the rotation-independent model of Reiners & Christensen (2010) to their model where the planetary magnetic moment is dependent on rotation, and thus tidal locking has an influence. They find radio fluxes of 180 and 300 mJy for the rotation-independent and the rotation-dependent model, respectively. Since the cyclotron frequencies calculated in this paper

are based on the magnetic moment predictions from these models, the maximum emission frequency and the radio flux densities are the same. Thus, we conclude that radio emission from Tau Bootis b should be detectable with LOFAR, UTR-2, the upcoming SKA (Square Kilometer Array), NenuFAR (New Extension in Nançay Upgrading LOFAR, currently under construction) (Grießmeier et al. 2011), and GURT (under construction in Kharkov, Ukraine Konovalenko et al. 2016). Also the VLA (Very Large Array), the LWA (Long Wavelength Array), and the GMRT (Giant Metrewave Radio Telescope) should be sensitive enough to allow a detection (Grießmeier et al. 2011).

Finally, we note that for HD 209458b radiative cooling can be neglected, whereas for HD 189733b it already has an effect. For details we refer to the study by Salz et al. (2015), who described HD 189733b as an intermediate case. We plan to perform a similar study as for Tau Bootis b for HD 189733b. Recently, Lalitha, Schmitt & Dash (2018) studied the atmospheric mass-loss of four close-in

Table 5. Summary of possibility for generation and/or escape of radio waves for the planets HD 209458b and HD 189733b (Weber et al. 2017a). The numbers in brackets are the maximum emission frequencies in MHz at the pole, assuming a planetary radius of 1.06 R_J .

	HD 209458b (pole)	HD 209458b (equator)	HD 189733b (equator)	HD 209458b (1 au)

planets around the very active stars Kepler-63, Kepler-210, WASP-19, and HAT-P-11. They found the XUV luminosities of these stars to be orders of magnitude higher than for the Sun. Lalitha et al. (2018) compared the four studied planets with HD 209458b and HD 189733b. All planets suffer extreme atmospheric mass-loss due to the strong XUV radiation from their host stars, very likely leading to the extended upper atmospheres and ionospheres, which might inhibit the escape of possibly generated radio emission.

5 CONCLUSIONS

We find that the supermassive hot Jupiter Tau Bootis b is clearly more favourable for the CMI than hot Jupiters like HD 209458b or HD 189733b studied previously. The main issue with the latter planets is the extended upper atmosphere and ionosphere, where exobase distances exceed the magnetospheric standoff distance, and upper atmospheres are in a hydrodynamic state for orbits < 0.2 au for Sun-like stars and < 0.5 au for more active stars (Weber et al. 2017a).

In general, we find that supermassive hot Jupiters like Tau Bootis b are much better candidates for future radio observations than classical hot Jupiters. There is no hydrodynamic outflow and the conditions for the CMI are very good, especially if compared to less massive hot Jupiters like HD 209458b or HD 189733b (0.69 and 1.142 Jupiter masses, respectively, from <http://exoplanet.eu>, accessed June 2018), where the atmospheric outflow is hydrodynamic. It is also worth to note that recently Daley-Yates & Stevens (2017, 2018) found the same result for ‘normal’ hot Jupiters as in Weber et al. (2017a, 2017b).

Considering our example planet Tau Bootis b, we can definitely say that objects with 5.84 M_J (Jupiter masses) keep their atmosphere compact due to their large gravity and thus lead to favourable conditions for the CMI. In follow-up studies we will investigate at which mass the transition to these conditions starts. This will include variations of the type of the star or the planetary radius. A further step in our follow-up studies will include an extension of the investigated magnetospheric regions beyond the exobase level up to the magnetopause.
