Naturaliste Plateau; volcanoclastic-rich sequence; subsidence; East Gondwana breakup; IODP Site U1513

Graphical abstract

Abstract

The Naturaliste Plateau is a submarine continental ribbon rifted from the southwest Australian margin during the Early Cretaceous breakup of East Gondwana. It occupied a key

position near the juncture of Greater India and the boundary between Australia and Antarctica. However, details of the Early Cretaceous evolution of the plateau are not well known because of limited data. Drilling at Site U1513 during IODP Expedition 369 recovered the first complete Lower Cretaceous succession on the eastern Naturaliste Plateau. The succession includes syn-rift volcanic rocks, Hauterivian to early Aptian volcanoclastic-rich sedimentary rocks, and Albian claystone strata. The 235-m thick volcanoclastic-rich sequence represents the missing post-breakup record in the southwest Australian rifted margin. It spans the transition from syn- to post-rift phase during the final stages of breakup between Greater India and Australia-Antarctica. We report the lithological, petrophysical, geochemical, paleontological, and paleomagnetic characteristics of the sequence, and then synthesize the results to define the Early Cretaceous depositional environment and subsidence history of the Naturaliste Plateau. From the early Hauterivian, weathered volcanic products were eroded and re-deposited locally as a volcanoclastic-rich sequence, with a major contribution from the southern Naturaliste Plateau. The depositional environment evolved from a shelf to upper bathyal condition during the Hauterivian through early Barremian with a decreasing sedimentation rate. This period is defined as a late syn-rift subsidence phase by NW-SE trending extension. After the final breakup with Greater India, the plateau remained at upper bathyal depths with little deposition until the early Aptian. Mid-lower bathyal depths inferred from the Albian claystone strata suggest that the post-rift thermal subsidence commenced during the late Aptian. This two-phase post-rift subsidence reflects the proximity or high temperature of mantle plume, possibly the Kerguelen plume, and its westward migration relative to the southwest Australian rifted margin.

1. Introduction

The Naturaliste Plateau is a large submarine continental block located 260 km west of the Australian continent (Fig. 1A; Borrisova, 2002; Halpin et al., 2008). It is underlain by thinned continental crust (20–25 km; Olierook et al., 2016) displaced from the southwestern Australian rifted margin, which is defined as a continental ribbon (Peron-Pinvidic and Manatschal, 2010). The Naturaliste Plateau is separated from the Australian continent by the Naturaliste Trough to the east, which is a bathymetric feature overlying the deep-water Mentelle Basin, and by the Perth Basin, which is a rift basin located beneath the continental shelf (Fig. 1). During the Early Cretaceous breakup of East Gondwana, the Naturaliste Plateau occupied a key position near the juncture of what would become the Greater Indian, Australian and Antarctic plates (Fig. 2A), and was also near the projected position of the Kerguelen plume (Gaina et al., 2007; Gibbons et al., 2012, 2013; Veevers et al., 1991; Whittaker et al., 2013; Williams et al., 2011). Its tectonic history thus is central to understanding the breakup of East Gondwana and the role of the Kerguelen plume on continental rifting. However, the Early Cretaceous evolution of the Naturaliste Plateau during and after the breakup has not been well established due to limited drilling and sparseness of geophysical data (Borrisova, 2002; Borrisova et al., 2010).

During International Ocean Discovery Program (IODP) Expedition 369, five boreholes were drilled at Site U1513 on the eastern flank of the Naturaliste Plateau (Fig. 1; Huber et al., 2019). A primary goal of the expedition was to recover the Cretaceous sedimentary succession and the first in-situ samples of underlying volcanic rocks, which provide stratigraphic control on the age and nature of the post-breakup succession in the southwest Australian rifted margin. In composite, drilling at Site U1513 recovered a succession of Cretaceous strata from the late Valanginian to the Campanian (Huber et al., 2019). The Early

Cretaceous succession at Site U1513 includes the syn-rift volcanic rocks overlying the breakup unconformity, Hauterivian to early Aptian sedimentary rocks containing abundant volcanic clasts, and Albian claystone strata (Fig. 1B). In particular, the 235 m-thick volcanoclastic-rich sequence at Site U1513 provides the first complete record that spans the transition from syn- to post-rift phase during the final stages of breakup between Greater India and Australia-Antarctica. It represents the missing stratigraphic record of post-breakup events in the onshore southwest Australian rifted margin (Norvick, 2004; Olierook et al., 2015c). Using a combination of shipboard and post-expedition data, we describe and interpret the lithological, petrophysical, geochemical, paleontological, and paleomagnetic characteristics of the sequence, and then assess the depositional environment. Based on these results and inferences, we discuss the Early Cretaceous subsidence history of the Naturaliste Plateau and its implications for the post-breakup evolution of the southwest Australian rifted margin.

2. Geologic setting

The Naturaliste Plateau covers 90,000 km² in water depths of 2,000–5,000 m that are elevated up to 2,500 m above the surrounding seafloor (Fig. 1A; Borissova, 2002). It is bounded by transform margins to the north adjacent to the Perth Abyssal Plain and to the southwest along the Naturaliste Fracture Zone, and by a rifted margin on the west that formed during the final stages of separation between Greater India and Australia. Its eastern flank is covered by the western Mentelle Basin (water depths of 2,000–4,000 m; Fig. 1B). The southern edge of the plateau is a steep faulted margin that formed during Late Cretaceous rifting between Australia and Antarctica (Borissova, 2002; Borissova et al., 2010).

Seafloor spreading began on the Cuvier and Perth Abyssal Plains and western Australian margins to the north of the Naturaliste Plateau during the late Valanginian, and propagated

westwards through the Hauterivian (Fig. 2A). The spreading ridge in the Perth Abyssal Plain established the western edge of the plateau during the early Barremian, which marked the final separation between Greater India and Australia-Antarctica (Colwell et al., 1994; Direen et al., 2008; Gaina et al., 2007; Gibbons et al., 2012, 2013; Markl, 1978; Olierook et al., 2015a; Veevers and Li, 1991; Williams et al., 2013). The late rifting stage was accompanied by volcanic eruptions on sections of the conjugate continental margins around the periphery of the eastern Indian Ocean, as well as on continental blocks and oceanic plateaus (Fig. 2; Colwell et al., 1994; Direen et al., 2008; Olierook et al., 2015a, 2017; Symonds et al., 1998; Whittaker et al., 2016; Zhu et al., 2009). On the southwest Australian rifted margin, basaltic rocks are exposed onshore as the Bunbury Basalt (Frey et al., 1996; Olierook et al., 2015b, 2016), and were dredged from the Naturaliste Plateau (Coleman et al., 1982; Direen et al., 2017; Mahoney et al., 1995). This volcanic activity was followed by deposition of volcanic-rich clastic sediments around the newly formed Indian Ocean (Sykes and Kidd, 1994; Vallier and Kidd, 1977) and along the Tethyan-Himalaya (Ghose et al., 2017; Hu et al., 2010), which during the Early Cretaceous was adjacent to the western margin of Australia (Fig. 2). The presence of a volcanoclastic-rich sequence on the Naturaliste Plateau was previously inferred from seismic reflection data (Borissova, 2002) and its topmost section cored at Deep Sea Drilling Project (DSDP) Site 258 (Davies et al., 1974), which is located 1.1 km west-southwest of Site U1513 (Fig. 1A).

3. Materials and methods

IODP Expedition 369 drilled five holes at Site U1513 (Latitude 33°47.62'S, Longitude 112°29.13'E at Hole U1513D) (Huber et al., 2019). Core recovery was 80.5% and reached a total depth of 774.0 meters below seafloor (mbsf) at Hole U1513E. The core-sections were systematically described aboard the ship at the macroscopic scale, and smear slides and thin-

sections were described at the microscopic scale. After the expedition, the core-sections of the volcanic and volcanoclastic-rich sequences were re-examined at the Kochi Core Center (KCC), Japan, and additional thin-sections were described. Lithology, mineralogical composition, grain size, sedimentary structures, bed thickness, and paleontological observations from shipboard data were augmented and revised by post-expedition analyses.

Bulk rock X-ray fluorescence (WD-XRF) composition analysis of 129 samples from Site U1513 was conducted using AXIOS Plus (Panalytical) at Institute for Chemistry and Biology of the Marine Environment (ICBM) of the Carl von Ossietzky University after the expedition. Borate glass beads were prepared from the sample powder using di-lithium tetraborate as a flux (700 mg sample, 4.2 g flux). Six additional samples of the volcanoclastic-rich sequence were analyzed using AXIOS (Panalytical) at Chonnam National University. Pellets were prepared from the sample powder mixed with wax binder (3 g sample, 0.3 g wax $C_{18}H_{36}O_2N_2$). Whole-rock X-ray diffraction (XRD) measurement and mineral identification were conducted during the expedition (Huber et al., 2019). After the expedition, whole-rock XRD was measured and identified for nine additional samples of the volcanoclastic-rich sequence at Korea Basic Science Institute (KBSI) using a D8 Advance diffractometer with a Cu source, voltage of 40 kV, current of 40 mA and measurement range of 8° – $80^{\circ}2\theta$.

Selected samples were analyzed for calcareous nannofossils and planktonic and benthic foraminifera during the expedition (Huber et al., 2019). Only benthic foraminiferal specimens were recovered from the volcanoclastic-rich sequence. After the expedition, eight samples were analyzed for palynomorphs at Korea Institute of Geoscience and Mineral Resources (KIGAM), using a standard palynological pretreatment method. The palynomorphs were identified based on illustrations and associated with taxonomic descriptions from the Perth

Basin (Backhouse, 1988) by MGPalaeo. Shell fragments in the volcanoclastic-rich sequence were identified from shipboard photographs at the Smithsonian Institution.

Porosity values measured during the expedition (Huber et al., 2019) were used to estimate the compaction trend for the Cretaceous succession at Site U1513. The trend was used to reconstruct the sedimentation rate and subsidence curve with the BasinVis 2.0 program (Lee et al., 2019, in press). Magnetic susceptibility was measured on the split-core surface (2.5 cm interval measurement) during the expedition (Huber et al., 2019). Natural remanent magnetization (NRM) was measured and stepwise demagnetized on all core-sections and selected discrete samples during the expedition (Huber et al., 2019). Geomagnetic polarity reversal sequences were identified from the magnetic inclinations at 20 mT alternating field and were correlated to the Geomagnetic Polarity Time Scale (Ogg et al., 2012, 2016).

4. Results and interpretation

4.1. Lithostratigraphy of Site U1513 and geochemical discrimination

The cored section from Site U1513 is divided into six Lithostratigraphic Units, I to VI (Fig. 3A; Huber et al., 2019). The lowermost Unit VI consists of alternating altered basaltic flows and volcanoclastic rocks, cut by multiple dolerite dikes. Vesicular texture with brown to red colored oxidation is dominant in the basalt flows, which indicate volcanic eruption and emplacement in subaerial to shallow water setting (Huber et al., 2019; Tejada et al., in press). Strong seismic reflectors from the volcanic sequence (Fig. 1B) are manifest throughout the Naturaliste Plateau and the western Mentelle Basin (Borissova, 2002; Borissova et al., 2010). The volcanoclastic-rich sedimentary sequence is Unit V at Site U1513, which we correlated to Unit V of DSDP Site 258 (an 11 m thick glauconitic sandstone with lithic fragments and detrital claystone; Davies et al., 1974) (Fig. 3A). The boundary between Units VI and V,

cored in Hole U1513E (interval 2R-4, 0–3 cm), is defined by an irregular contact with an altered basalt flow (Tejada et al., in press). Seismic reflection data show that Unit V is present only to the Naturaliste Plateau (Fig. 1B). Units IV to III consist of Albian to Cenomanian claystone strata, and Units II to I comprise Upper Cretaceous to Neogene chalk and ooze. The boundary between Units V and IV occurs at a transition from sandstone to claystone and coincides with a decrease in magnetic susceptibility (Fig. 3A). Unit IV to Unit I thicken eastward from the flank of the Naturaliste Plateau into the western Mentelle Basin, and from there thin further eastward over the eastern Mentelle Basin and Yallingup Shelf (Fig. 1B).

Previous studies (e.g., Coleman et al., 1982) have correlated Unit V at Site 258 laterally with Unit IV at DSDP Site 264 (altered volcanoclastic conglomerates; Hayes et al., 1975), which is located near the southern edge of the Naturaliste Plateau (Fig. 1A). However, the lithological characteristics of Unit IV at Site 264 (volcanic pebbles and granules embedded in highly altered clayey to sandy or tuffaceous matrix; Ford, 1975) are inconsistent with Unit V of Sites U1513 and 258. The volcanoclastic conglomerate section at Site 264 is more similar to altered volcanoclastic flows intercalated with basalt flows of Unit VI at Site U1513 (Tejada et al., in press).

The Al-Zr-Ti ternary plot (Fig. 3B) discriminates the volcanoclastic-rich sedimentary rocks (Unit V) from sediments and sedimentary rocks of Units I to IV and from the basalt flows and volcanoclastic beds of Unit VI. Relatively high Ti contents of Units V and VI are attributed to the presence of volcanic clasts and minerals such as pyroxene. However, the Al-Zr-Ti composition of Unit V cannot be explained by a simple mixture of weathered volcanic materials derived from the underlying volcanic rocks (Unit VI) with clay minerals (represented by Al), because of their relatively high Zr contents. The composition of Unit V

may be attributed to volcanic material sources with relatively high Zr content, similar to the basalt fragments dredged from the southern Naturaliste Plateau (Fig. 3B). Alternatively, a winnowing effect induced by bottom currents may lead to heavy mineral enrichments (e.g., zircon) compared to clay minerals (e.g., Atar et al., 2019; Schnetger et al., 2000).

4.2. Lithostratigraphic subunits of Unit V

The 235.33 m-thick volcanoclastic-rich sequence (Unit V) at Site U1513 was recovered between 454.92 to 690.25 mbsf (interval U1513D-41R-4, 90 cm, through 66R-1, 8 cm) in Hole U1513D and from 685.2 to 688.07 mbsf (interval U1513E-2R-1, 0 cm, through 2R-3, 100 cm) in Hole U1513E. We subdivide the volcanoclastic-rich sequence into four Subunits 1–4, numbered from the top downward (Fig. 4A). The major lithological characteristics and sedimentary facies of each subunit are as follows (core-section images in Fig. 4B). Subunit 4 (554.77–690.25 mbsf) consists of coarse to fine-grained, angular to sub-rounded greenish-black, gray to dark/reddish/greenish gray sandstones and dark gray clayey sandstones with abundant glauconite. These are interbedded with siltstone, clayey siltstone, silty claystone, and silty sandstone layers. This subunit is generally massive with a few layered intervals containing parallel or cross laminations. There are a few examples of normal or inverse grading, slump facies, ripples, and soft-sediment deformation. Subunit 3 (498.47–554.77 mbsf) is massive and consists of dark gray to greenish-black siltstones and dark gray silty claystone with sub-angular to sub-rounded grains. Within this unit, grain sizes vary from clay to very fine sand. Subunit 2 (472.18–498.47 mbsf) is a dark reddish-gray silty claystone with sub-angular and sub-rounded grains. This subunit exhibits parallel laminations, and normal grading is evident in interbedded coarse to fine-grained sandstone layers. Subunit 1 (454.92–472.18 mbsf) is gray to dark greenish-gray, coarse to fine-grained sandstone with angular to

sub-rounded grains. The sandstone is generally massive with interbeds containing parallel or cross laminations. A few intervals exhibit normal grading.

The volcanic clasts and lithic fragments are abundant throughout Unit V, and are evident macroscopically in the sandstones of subunit 4 (Fig. 4B and C). Ca and Na-rich feldspar (e.g., labradorite), montmorillonite, and chlorite are dominant throughout the sequence, while kaolinite is dominant in the silty claystone of subunit 2 (Supplementary material 1). These minerals are attributed to weathering and erosion of volcanic rocks and materials (e.g., Bain et al., 1980; Hathon and Underwood, 1991; Sykes and Kidd, 1994). Primary ash or pyroclastic layers were not observed in Unit V. It is thus interpreted to consist of epiclastic deposits, which are not deposited by explosive volcanism and its direct effects (e.g., pyroclastic flow) (Manville et al., 2009 and references therein). Hydrothermal alteration is observed throughout Unit V with a few hydrothermal veins. Calcite cementation is present in subunits 1, 3, and 4 filling inclined and irregular shaped veins with minor fault offsets and slickensides. Pyrite nodules are present throughout all four units with carbonate and siderite nodules present only in subunit 3.

4.3. Paleontological observations

Bioturbation and organic matter are common in subunits 4 and 3 of Unit V, decreasing upward in the section (Fig. 4C). Subunit 4 shows intense bioturbation and trace fossils (e.g., *Macaronichnus*, *Teichichnus*) with burrows, borings and horizontal structures indicative of the *Skolithos* and *Cruziana* ichnofacies that are typically present from the low-tide zone to the edge of the continental shelf (Knaust, 2017; Seilacher, 1967). A few trace fossils and bioturbated lamination contacts are observed in subunits 2 and 1. Shell fragments are abundant in subunits 4 and 3 (Fig. 4C). Shell fragments are 2–4 mm thick and up to several centimeters long but are generally too fragmented and/or not exposed well enough on cut or

broken core surfaces to be confidently identified. Two individuals were identified as *Neithea* sp. and a third, tentatively, as *Cteniopleurium* sp. The former is a fairly common Lower Cretaceous genus (Hayami, 1975), whereas the latter was originally described from the Santonian Gingin Chalk of Western Australia (Feldtman, 1951). If the generic identification of the latter is correct, this would be the first occurrence of this taxon from Lower Cretaceous strata. Both are found in inner to middle shelf environments and interior basins. Plant debris is present throughout Unit V and abundant in subunit 4.

Benthic foraminiferal specimens with limited biostratigraphic and paleoenvironmental significance were recovered in subunits 4 and 3 of Unit V. Specimens of *Praebulimina* sp. and *Lenticulinella* sp. are identified from Samples U1513D-50R-CC (543.98 mbsf) and U1513D-52R-CC (564.43 mbsf). A specimen of *Quinqueloculina?* sp. was recovered from Sample U1513D-48R-CC (525.76 mbsf). Benthic foraminifera present belong to the opportunistic, environmentally tolerant benthic taxon *Lenticulina* spp., the resilient taxon *Praebulimina* sp., and the miliolid taxon *Quinqueloculina?* sp. (Holbourn et al., 1999; Reolid and Martínez-Ruiz, 2012). These benthic foraminiferal taxa have extensive depth ranges from inner neritic to lower bathyal, but their highest abundance is found in outer shelf environments (Gräfe and Wendler, 2003; Holbourn and Moullade, 1998; Murray, 1991, 2006). In the overlying Unit IV, agglutinated foraminiferal taxa are dominant with *Glomospira* spp. and the most abundant taxa, *Kalamspis* sp. and *Nothia* sp. Few calcareous benthic foraminiferal markers for deep-sea environments (*Gavelinella* sp., *Cibicidoides* spp., *Osangularia* spp.) are present in some cores. The benthic foraminiferal assemblage in Unit IV indicates middle to lower bathyal depths as well as an open marine depositional environment (Kaminski and Gradstein, 2005; Tjalsma and Lohmann, 1983; van Morkhoven et al., 1986).

In several samples of Units V and IV, a few dinoflagellate cysts, phytoclasts, spores and pollen were identified (Fig. 4C). Subunit 3 of Unit V includes specimens of *Leptodinium/Impagidinium* sp. (Sample U1513D-50R-1, 33–35 cm; 536.94 mbsf), and *Apteodinium* sp. and *Circulodinium hystrix/vannophorum* (Sample U1513D-46R-3, 61–63 cm; 501.62 mbsf). In the Perth Basin (Fig. 1A), *Apteodinium* sp. has an age range from the Hauterivian to the Aptian, although Backhouse (1988) estimates a longer range for this taxon. *Circulodinium hystrix/vannophorum* has an age range from the Valanginian to the Aptian (Backhouse, 1988) and can be associated with marginal, brackish, coastal, nearshore environments with unstable conditions or high environmental stress (Carvalho et al., 2016). In the lowermost claystone of the overlying Unit IV (Sample U1513D-41R-1, 85–87 cm; 451.06 mbsf), *Spiniferites* sp., *Cribroperidinium edwardsii*, and *Apteodinium granulatum* are present (Fig. 4C). These taxa have age ranges that span the Early Cretaceous in the Perth Basin (Backhouse, 1988; Helby et al., 1987) and may suggest an inner neritic environment (Carvalho et al., 2016), although reworking from a source upslope is possible.

4.4. Magnetostratigraphy and sedimentation rate of Unit V

Well-defined magnetic polarity sequences allow us to establish a high resolution magnetostratigraphy and an age-depth model for the volcanoclastic-rich sequence (Fig. 5A; Supplementary material 2). The uppermost 0.5 m of the sequence correlates with the beginning of the long Cretaceous Normal Superchron, chron C34n (125.93–83.64 Ma) (Ogg et al., 2012), which extends upward into the lower part of Unit II (Huber et al., 2019). In the remainder of the volcanoclastic-rich sequence, between 690.25 and 455.47 mbsf, eighteen polarity sequences are distinguished, spanning chrons M10Nn.1n to M0r (134.48–125.93 Ma; Ogg et al., 2012). Unit V was thus deposited from the Hauterivian to the early Aptian (Ogg et al., 2016), and more than two thirds of total thickness of this sequence accumulated during

the Hauterivian (Fig. 5A). The beginning of chron M10Nn.1n (134.48 Ma) is missing at Site U1513. The chron ended at 134.22 Ma, giving a minimum age for the volcanic sequence of Unit VI. The boundary with underlying Unit VI is defined by a polarity reversal, as well as an irregular contact, which suggests a time gap between the volcanoclastic-rich deposition and the topmost basalt flow.

The magnetostratigraphy of Unit V allows a detailed reconstruction of the sedimentation rate. The strata within each geomagnetic polarity epoch were decompacted to determine layer thickness prior to burial using the onsite compaction trend and BasinVis 2.0 program (Supplementary material 2; Lee et al., in press). The decompacted thickness was combined with the duration of each geomagnetic chron to reconstruct the sedimentation rate. The sedimentation rate varies, but shows an overall decrease upward in the section (Fig. 5B). High sedimentation rates are recorded in the early Hauterivian, during chrons M10Nn.1n (<134.48–134.22 Ma; >183 m/myr), M10r (134.22–133.88 Ma; 298 m/myr) and M9r (133.58–133.3 Ma; 136 m/myr). The sedimentation rate for chron M10Nn.1n is a minimum rate, as the bottom (oldest) part of the chron is not recovered in the core. The sedimentation rate is much lower from the late Hauterivian to early Aptian, ranging from 1 to 40 m/myr.

Recent studies have suggested new ages for the geomagnetic chrons in the Valanginian to Aptian stages, based on numerical U-Pb and Ar-Ar ages intercalibrated with astrochronology (Aguirre-Urreta et al., 2015, 2019; Martinez et al., 2015; Olierook et al., 2019c). With a difference of 3.5 to 5.5 m.y., these ages are substantially younger than those proposed in the Geologic Time Scale of Ogg et al. (2012, 2016), which suggest <130.9–122.3 Ma for chrons M10Nn.1n to M0r of Unit V (Supplementary material 3). It suggests ~130.5 Ma as a minimum age of the underlying volcanic sequence. The relatively consistent shift of ages maintains the major trends in the age-depth model and sedimentation rate of Unit V.

5. Discussion

5.1. Early Cretaceous depositional environment

The age of the volcanoclastic-rich sequence at Site U1513 (134–126 Ma) overlaps with the ages of volcanic rocks dredged from the Naturaliste Plateau (132–128 Ma; Direen et al., 2017), indicating that the deposition of Unit V was coincided with volcanism on the plateau. However, no direct evidence of explosive volcanic eruption (e.g., ash, pyroclastic flows) was observed in Unit V, and the volcanic clasts and lithic fragments are relatively fine-grained and round-shaped (Fig. 4C). The volcanic component is therefore interpreted to indicate transport from distant volcanic terrains. Based on volcanic edifices imaged on seismic reflection profiles (Borissova, 2002), candidate sources of the volcanic materials in Unit V are the exposed equivalents of the underlying volcanic sequence (Unit VI) and the volcanic terrains of the southern and northern Naturaliste Plateau. We argue that the southern Naturaliste Plateau is a major source of the volcanic materials for the following reasons. Firstly, relatively fine and sub-rounded volcanic grains throughout Unit V (Fig. 4C) indicate a distant source (>125 km to the southern margin from Site U1513). Secondly, the high Zr content in Unit V suggests derivation from volcanic rocks with higher Zr content than Site U1513 basalts (Fig. 3B). Thirdly, sediment provenances and distribution paths trending parallel to the rift axis are observed in rift basins (e.g., Perth Basin; Olierook et al., 2019a). In the case of the Naturaliste Plateau, the trend points to the southern volcanic terrain as the provenance source.

Montmorillonite, found throughout Unit V, is interpreted to be the result of subaerial weathering and erosion of volcanic rocks. This is consistent with the environmental setting interpreted from the volcanoclastic conglomerate sequence at Site 264 in the southern Naturaliste Plateau. The poorly sorted volcanic fragments and lack of mixing with non-

volcanic detritus are indicative of a volcanoclastic flow deposit sourced from nearby volcanic terrain, rather than transported by water (Ford, 1975). The adjacent source terrain is potentially part of the volcanic rocks on the southern Naturaliste Plateau, which is supported by the similar geochemical composition between volcanic cobbles at Site 264 and dredged basaltic samples (Fig. 3B). However, alteration involving seawater interaction described from a few volcanic fragments at Site 264 (Ford, 1975) are indicative of subaqueous setting. We interpret that the volcanic terrains on the southern Naturaliste Plateau were emplaced and weathered in a fluctuating environment between subaerial and shallow-water settings. This environmental setting could contribute to the type of clay mineral alteration, subaerial erosion, and subsequent transport to the site of the volcanoclastic-rich deposition on the eastern Naturaliste Plateau.

Paleontological evidence from benthic foraminifera, bivalves, palynomorphs as well as trace fossils suggests a shelfal to shallow bathyal depositional environment for the early Hauterivian to early Barremian (subunit 4 to 3 of Unit V). Together with the regularly changing sedimentary facies and sedimentation rate, the data from benthic foraminiferal assemblages suggest a restricted and shallow marine environment displaying unsteady conditions for the lower part of Unit V. Alternating environmental characteristics, such as variations in oxygenation, nutrient supply or alkalinity, can induce high environmental stress, which makes a habitat unsuitable for most foraminiferal taxa and might result in the depletion of the benthic foraminiferal assemblage and a reduction to few tolerant taxa, respectively. This analysis corresponds to the paleoenvironmental interpretation from palynomorph specimens. Paleontological evidence from the lower part can therefore be interpreted to indicate a marginal marine environment with variations in the terrigenous input, runoff and chemical composition of coastal waters, and changes in shape and nature of the basin area.

The interpretation of an unstable depositional environment is furthermore supported by the highly variable Mg/Al and Rb/Al ratios (Fig. 5C), which can be used to infer changes in environmental conditions (e.g., Atar et al., 2019; Martin-Puertas et al., 2010; Schnetger et al., 2000). Mg and Rb enrichments are associated with increases in terrigenous/detrital input, fluvial runoff or precipitation. The highly varying Mg/Al and Rb/Al ratios of the lower part (particularly subunit 4) correlate with the interval of high sedimentation rate. The correlation strongly suggests considerable input from a land mass.

The upper part of Unit V (subunits 2 and 1) was likely deposited in deeper water depths than the lower part, as indicated from the sparsity of fossils and bioturbation, lower sedimentation rate (1–23 m/myr), and lower terrigenous influence inferred from the Mg/Al ratio (Fig. 5C). The depth increase could be enhanced by a rise in global sea-level (~60 m; Fig. 6A) during the Hauterivian, which culminated in a highstand during the Barremian (Haq, 2014). We infer that the upper part was deposited in an upper bathyal environment (200–600 m), which is deeper than the shallow marine of the lower part, but not as deep as the middle to lower bathyal depths (600–2,000 m) of Unit IV. Together with the changes in the benthic foraminiferal assemblage, a significant increase in water depth between Unit V and Unit IV is suggested by the lithologic transition to marine claystone, the absence of volcanic clasts and lithic fragments, and the abrupt decrease in Ti content and magnetic susceptibility.

5.2. Subsidence history and implications for the post-breakup evolution of the southwest Australian rifted margin

5.2.1. Syn-rift subsidence phase

Previous studies (e.g., Borissova, 2002) have interpreted the Hauterivian to early Barremian sequence of the Naturaliste Plateau as a post-rift thermal subsidence phase. However, we

attribute the interval to the syn-rift subsidence phase. During the early Hauterivian, the Naturaliste Plateau subsided fast (~ 370 m/myr), but high sedimentation rate kept pace with subsidence and maintained the depositional environment in a shallow marine condition (Fig. 6B). The depth increased to an upper bathyal setting through the early Barremian. This subsidence period corresponds to the NW-SE trending extension during 7–8 m.y., led by seafloor spreading in the Perth Abyssal Plain and its westward propagation along the northern margin of the Naturaliste Plateau (Fig. 2A; Gibbons et al., 2012; Hall et al., 2013; Williams et al., 2013). In seismic profiles (Borissova, 2002; Borissova et al., 2010; Maloney et al., 2011), NE-SW trending faults parallel to the seafloor magnetic anomalies and syn-rift structures (e.g., synsedimentary deformation, fault reactivation) are observed in the Hauterivian–Barremian strata of the Naturaliste Plateau and the Mentelle Basin. Core-sections of Unit V contain multiple fault offsets in subunits 4 and 3. During this phase, the syn-rift volcanism diminished on the Naturaliste Plateau and the onshore southwest Australian margin (Fig. 6B). Most of the Hauterivian to early Barremian strata at Site U1513 are thus a late syn-rift sequence. This syn-rift phase indicates ~ 550 m of basement subsidence in addition to the ~ 60 m sea-level rise that occurred during this time (Fig. 6), which we attribute to the crust thinning during the extension.

The deepening trend from the late Valanginian (volcanism near sea-level; Unit VI) through the early Barremian at Site U1513 is similar to that observed in the South Perth Shale in the Vlaming Sub-basin of the southern Perth Basin (Fig. 1A). The South Perth Shale was deposited during a marine transgression and a highstand from the late Valanginian to Barremian (Lech et al., 2016). In the eastern Mentelle Basin, the Late Jurassic syn-rift fluvio-lacustrine deposits transition upward into marine strata (Lithostratigraphic Units IIb and IIa at

Site U1515), indicating subsidence and marine transgression from the Valanginian (Wainman et al., in press).

5.2.2. Two-phase post-rift subsidence process

Classical rift models predict significant thermal subsidence immediately following continental breakup in response to lithospheric cooling in early post-rift time (McKenzie, 1978). After the final breakup between Greater India and Australia-Antarctica during the early Barremian, however, the Naturaliste Plateau remained at upper bathyal depths with low sedimentation rate through to the early Aptian (Fig. 6B). On the southern Perth Basin, faulting and sedimentation ceased virtually from the Barremian (Norvick, 2004; Olierook et al., 2015c). These observations indicate that the southwest Australian rifted margin did not immediately begin to thermally subside after the final breakup during the late Barremian through the early Aptian (Post-rift phase 1; Fig. 6B). Mid–lower bathyal depths from the Albian at Site U1513 suggest the initiation of post-rift thermal subsidence during the late Aptian (Post-rift phase 2; Fig. 6B).

The lack of substantial post-rift thermal subsidence on the southwest Australian rifted margin could be induced by the effects of mantle plume (e.g., thermal buoyancy, mantle instability, small-scale convection; Boston et al., 2019; Dafoe et al., 2017). During this period, the margin might be located within a large influence radius of a mantle plume (500–1,000 km; White and McKenzie, 1989). Previous works suggest that contemporaneous volcanism along the rifted margins of Greater India (Comei-Cona) and Australia (Bunbury Basalt), together with that on the Naturaliste Plateau (Fig. 2A) formed the 136–124 Ma Large Igneous Province (Direen et al., 2017; Olierook et al., 2016, 2017, 2019b; Watson et al., 2016; Zhu et al., 2009). The scattered mafic rocks across the margins have been explained by either disconnected limbs of the Kerguelen plume or multiple mantle plumes (Coffin et al., 2002;

Olierook et al., 2016; Whittaker et al., 2016). The proximity or elevated temperature of the Kerguelen plume and/or other plume(s) could account for the relatively shallow depths of the Naturaliste Plateau during the late Barremian through early Aptian. This may be responsible for the latest volcanism (~128 Ma; Direen et al., 2017) and hydrothermal alteration age at Site 264 (128–123 Ma; Olierook et al., 2017) on the southern Naturaliste Plateau, and hydrothermal veins in subunit 1 of Unit V at Site U1513. Alternatively, a transient thermal anomaly associated with the slow rifting between the Australian and Antarctic plates (Direen et al., 2007) may have kept the southwest Australian margin elevated during the period. However, it is uncertain if this mechanism can explain the onset of thermal subsidence during the late Aptian, which preceded the plate motion change (~100 Ma; Whittaker et al., 2013) and seafloor spreading (~83 Ma; Sayer et al., 2001) between Australia and Antarctica.

The post-rift thermal subsidence began during the late Aptian (>54 m/myr; Fig. 6B). The period corresponds to the onset of extensive magmatic activity associated with the volcanism on the Kerguelen Plateau (≥ 119 Ma; Coffin et al., 2002) and the Gulden Draak Knoll (~117 Ma; Whittaker et al., 2016). It resulted from the westward migration of the Kerguelen plume relative to the southwest Australian margin and associated relocation of spreading center and ridge jumps during the opening of Indian Ocean (Fig. 2B; Gibbons et al., 2012; 2013; Olierook et al., 2017, 2019b; Watson et al., 2016). The relative westward migration of the Kerguelen plume could have removed the thermal buoyancy support on the rifted margin, which triggered the thermal relaxation of thinned lithosphere and the thermal subsidence. This is marked by the extensive deposition of the Albian claystone in an open marine environment, which blanketed most of the Naturaliste Plateau and the Mentelle Basin (Fig. 1B). In seismic profiles, the strata are mostly unfaulted and thicken into the western Mentelle Basin with pinch-out and onlap on the eastern Naturaliste Plateau and the eastern Mentelle

Basin through to the Yallingup Shelf (Borissova, 2002; Borissova et al., 2010; Maloney et al., 2011). The thick claystone strata in the western Mentelle Basin are likely derived from high thermal subsidence rates, corresponding to significantly thinned crust (~13 km) beneath the Naturaliste Trough (Johnston et al., 2010; Olierook et al., 2016).

6. Conclusions

A 235 m-thick volcanoclastic-rich sedimentary sequence was recovered at IODP Site U1513 on the eastern flank of the Naturaliste Plateau, rifted from the southwest Australian continental margin. The volcanoclastic-rich sequence provides a new and in-depth record of the Early Cretaceous stratigraphy and changes in the depositional environment immediately after the onset of seafloor spreading in the Perth Abyssal Plain. Magnetostratigraphy indicates the deposition during the Hauterivian through early Aptian, which spans the final stages of breakup between Greater India and Australia-Antarctica. The sequence contains abundant volcanic clasts, lithic fragments and clay minerals derived from subaerial weathering and erosion of volcanic products. The coeval volcanic rocks on the southern Naturaliste Plateau are inferred to be a major source of the volcanic materials. A synthesis of sedimentological and paleontological observations, as well as geochemical data, indicates a transition of a shelf to upper bathyal environment with a decreasing sedimentation rate. Our results highlight the Early Cretaceous subsidence history of the Naturaliste Plateau. We define a syn-rift subsidence interval and the two-phase post-rift subsidence process across the southwest Australian rifted margin. During the Hauterivian through early Barremian, the depositional environment evolved from a shelf to upper bathyal setting with decreasing terrestrial input. This progressive deepening corresponds to the syn-rift subsidence by a NW-SE extensional regime, which is associated with the seafloor spreading in the Perth Abyssal Plain and its westward propagation. After the final breakup with Greater India to the west of

the Naturaliste Plateau, the region remained at upper bathyal depths with low sedimentation rate during the late Barremian through early Aptian. This interpretation suggests that the southwest Australian rifted margin had a lack of substantial post-rift thermal subsidence following the final breakup. This pause in subsidence could be induced by the proximity or high temperature of the Kerguelen plume and/or other mantle plume(s). Mid-lower bathyal depths indicated from the extensive Albian claystone strata suggest that the post-rift thermal subsidence commenced during the late Aptian, which corresponds to a period of westward migration of the Kerguelen plume relative to the southwest Australian rifted margin and associated relocation of spreading center and ridge jumps.

Acknowledgements

This research used data and samples provided by the International Ocean Discovery Program (IODP). We thank technical staffs of IODP Expedition 369 and crew members of the *JOIDES Resolution* for their critical contributions, and Geoscience Australia for providing us with invaluable data. We acknowledge financial support by K-IODP by the Ministry of Oceans and Fisheries and KRF program by the Ministry of Science and ICT through the NRF of Korea (2017H1D3A1A01054745) to E.Y.L., Brian J. O'Neill Memorial Scholarship to E.W., J-DESC to M.L.G.T., U.S. Science Support Program Post-Expedition Research Award (70GG00939) to D.L.H., ANZIC supported by the Australian Government through the ARC LIEF Grant (LE160100067) to C.C.W., A.M. and L.W., and ECORD and IODP-France to L.R. and M.M. Special thanks go to Daniel Mantle and Adam Charles (MGPaleo) for palynological analysis, to Michael Wagreich, Susanne Gier and the KBSI Gwangju Center for sample analysis, and to Yusuke Kubo, Shigako Nigi and Ryo Yamaoka of the KCC for facilitating our visit and core descriptions (Request No. 071241IODP). We thank C. Lehnert and E. Gruendken from the Microbiogeochemistry group at the ICBM for sample preparation and XRF analysis. This manuscript was improved significantly from the thorough reviews of H.K.H. Olierook, two anonymous reviewers and the editorial handling of M. Santosh.

Figures

Figure 1. A) Map of Naturaliste Plateau (NP), Mentelle Basin (MB), and southern Perth Basin with respect to mainland Australia (inset) (revised from Borissova, 2002), showing locations of IODP Sites U1513, U1515 (yellow circles), DSDP Sites 258, 264 (white circles), faults (grey lines) and a seismic section (red line, shown in B). The bathymetric contour interval is 500 m and the Naturaliste Plateau is defined approximately by the 4000-m contour. B) Seismic line S310/07 (provided by Geoscience Australia) showing Site U1513 location, general lithostratigraphy, the extent of the volcanoclastic-rich sequence (yellow shade), projected location of Site U1515, and structural characteristics. Dashed green line indicates bottom of the Albian strata.

Figure 2. Plate reconstruction of the Naturaliste Plateau (N) and surrounding regions with IODP Site U1513 location (green star) at 130 Ma, 120 Ma, 100 Ma (revised from Gibbons et al., 2012). Volcanic rock occurrences (red areas) and volcanoclastic deposit sites (orange dots) are inferred from previous studies (Borissova et al., 2003; Direen et al., 2017; Ghose et al., 2017; Hayes et al., 1975; Hu et al., 2010; Olierook et al., 2015a, 2015b; Whittaker et al., 2016; Zhu et al., 2009). AAP: Argo Abyssal Plain, BB: Bunbury Basalt, BK: Batavia Knoll, BR: Bruce Rise, CAP: Cuvier Abyssal Plain, CB: Comei Basalt, E: Exmouth Plateau, EB: Elan Bank, GAP: Gascoyne Abyssal Plain, GK: Gulden Draak Knoll, K: Kerguelen Plateau, M: Mentelle Basin, P: Perth Basin, PAP: Perth Abyssal Plain, RSB: Rajmahal–Sylhet Basalt, W: Wallaby Plateau, Z: Zenith Plateau.

Figure 3. A) Lithostratigraphic profiles of IODP Site U1513 and DSDP Sites 258, 264 drilled on the Naturaliste Plateau (Davies et al., 1974; Hayes et al., 1975; Huber et al., 2019), together with ages and magnetic susceptibility (ms) of Site U1513. B) Al-Zr-Ti ternary plot for sediments, sedimentary and volcanic rocks recovered from Site U1513. Values for Al (multiplied by 10), Ti (multiplied by 100) in wt% and Zr in ppm are normalized to 100%. Factors for Al and Ti were used to position the dots closer to the middle of the diagram. Yellow dots are data from the volcanoclastic-rich sequence of Unit V. For Unit VI, red circle represents mean data from basalt and dolerite dike samples, and red dots are data from volcanoclastic beds. Open circles present the mean data from volcanic rocks; dredged samples (Direen et al., 2017) and volcanic fragments at Site 264 (Ford, 1975) of the southern Naturaliste Plateau (SNP; pink), dredged samples (Coleman et al., 1982; Mahoney et al., 1995) of the northern Naturaliste Plateau (NNP; orange), and outcrop samples (Olierook et al., 2016) of the Bunbury Basalt (BB; brown).

Figure 4. A) Lithologic profile of the volcanoclastic-rich sequence (Unit V) with Hole U1513D core numbers and Subunits 1–4. B) Core-section images. Subunit 1: massive sandstone with volcanic clasts and calcite cementation (462.02–462.32 mbsf; interval U1513D-42R-2, 80–110 cm) and low angle to planar stratified sandstone with pyrites (464.58–464.88 mbsf; interval U1513D-42R-4, 100–130 cm), Subunit 2: silty claystone with interbedded sandstone layers and soft-sediment deformation (494.36–494.66 mbsf; interval U1513D-45R-5, 60–90 cm), Subunit 3: massive sandy siltstone with slight bioturbation and pyrites (540.27–540.57 mbsf; interval U1513D-50R-3, 65–95 cm), Subunit 4: massive glauconitic sandstone with volcanic clasts and lithic fragments (636.37–636.67 mbsf; interval U1513D-60R-4, 63–93 cm) and low angle to planar stratified clayey sandstone with volcanic

clasts, bioturbation and pyrites (598.07–598.37 mbsf; interval U1513D-56R-3, 103–133 cm).

C) Macroscopic and microscopic observations of distribution of volcanic clasts, lithic fragments, bioturbation, shell fragments, plant debris and unidentified organic matter. Images of pollens, volcanic clasts (thin-section image; Sample U1513D-42R-2, 138–143 cm), shell fragments, plant debris and trace fossils. *S*: *Spiniferites* sp., *Ce*: *Cribroperidinium edwardsii*, *Ag*: *Apteodinium granulatum*, *Ch/v*: *Circulodinium hystrix/vannophorum*, *A*: *Apteodinium* sp., *L/I*: *Leptodinium/Impagidinium* sp.

Figure 5. A) Magnetostratigraphic age-depth model for the volcanoclastic-rich sequence (Unit V) of Hole U1513D (Huber et al., 2019 with ages from Ogg et al., 2012, 2016). Eighteen magnetic polarity reversals from chrons M10Nn.1n to M0r between 690.25 and 455.47 mbsf. Lithologic profile and subunit ranges of Unit V are from Fig. 4A. B) Sedimentation rate vs. age plot with a lithologic profile based on magnetostratigraphic units. Dashed pink lines are evaluated from present (compacted) layer thickness, and solid lines from restored (decompacted) layer thickness. C) Mg/Al (in purple) and Rb/Al (in orange) ratios vs. age.

Figure 6. A) Early Cretaceous global sea-level (SL) curves (Haq, 2014). B) Early Cretaceous subsidence history of the Naturaliste Plateau at Site U1513 with Units VI to IV and subunits of Unit V. Subsidence curve represents the top depth of volcanic sequence, which is the accumulated thickness of volcanoclastic-rich strata in addition to estimated paleobathymetry. Major tectonic events are shown with volcanic eruption periods of the Naturaliste Plateau

(NP; Direen et al., 2017), Bunbury Basalt (BB; Olierook et al., 2016), Kerguelen Plateau (KP; Coffin et al., 2002) and Gulden Draak Knoll (GK; Whittaker et al., 2016).

Graphical abstract

Highlights

Lower Cretaceous strata at IODP Site U1513 on the Naturaliste Plateau span breakup.

Volcaniclastic-rich strata have a deepening record from shelf to upper bathyal depths.

A late syn-rift phase to two-phase post-rift subsidence history is revealed.
