Summary

Numerous processes such as metamorphic reactions, fluid and melt transfer and earthquakes occur at a subducting zone, but are still incompletely understood. These processes are affected, or even controlled, by the magnitude and distribution of stress and deformation mechanism. To eventually understand subduction zone processes, we quantify here stresses and deformation mechanisms in and around a subducting lithosphere, surrounded by asthenosphere and overlain by an overriding plate.

24 We use two-dimensional thermo-mechanical numerical simulations based on the finite difference and
25 marker-in-cell method and consider a 3200 km wide and 660 km deep numerical domain with a
26 resolution of 1 km by 1 km. We apply a combined visco-elasto-plastic deformation behaviour using a
27 linear combination of diffusion creep, dislocation creep and Peierls creep for the viscous deformation.
28 We consider two end-member subduction scenarios: forced and free subduction. In the forced
29 scenario, horizontal velocities are applied to the lateral boundaries of the plates during the entire
30 simulation. In the free scenario, we set the horizontal boundary velocities to zero once the subducted
31 slab is long enough to generate a slab pull force large enough to maintain subduction without
32 horizontal boundary velocities. A slab pull of at least 1.8 TN m^{-1} is required to continue subduction in
33 the free scenario. We also quantify along-profile variations of gravitational potential energy (GPE). We
34 evaluate the contributions of topography and density variations to GPE variations across a subduction
35 system. The GPE variations indicate large-scale horizontal compressive forces around the trench region
36 and extension forces on both sides of the trench region. Corresponding vertically-averaged differential
37 stresses are between 120 and 170 MPa. Furthermore, we calculate the distribution of the dominant
38 deformation mechanisms. Elasto-plastic deformation is the dominant mechanism in the upper region
39 of the lithosphere and subducting slab (from ca. 5 to 60 km depth from the top of the slab). Viscous
40 deformation dominates in the lower region of the lithosphere and in the asthenosphere. Considering
41 elasticity in the calculations has an important impact on the magnitude and distribution of deviatoric
42 stress; hence, simulations with increased shear modulus, in order to reduce elasticity, exhibit
43 considerably different stress fields. Limiting absolute stress magnitudes by decreasing the internal
44 friction angle causes slab detachment so that slab pull cannot be transmitted anymore to the
45 horizontal lithosphere. Applying different boundary conditions shows that forced subduction
46 simulations are stronger affected by the applied boundary conditions than free subduction
47 simulations. We also compare our modelled topography and gravity anomaly with natural data of
48 seafloor bathymetry and free-air gravity anomalies across the Mariana trench. Elasticity and deviatoric

stress magnitudes of several hundreds of MPa are required to best fit the natural data. This agreement suggests that the modelled flexural behaviour and density field are compatible with natural data. Moreover, we discuss potential applications of our results to the depth of faulting in a subducting plate and to the generation of petit-spot volcanoes.

1. - Introduction

Subduction zones are critical locations on Earth where the oceanic lithosphere dives into the convecting mantle and, hence, contributes to the cooling of the Earth and to the recycling of rocks and water (e.g. Stern, 2002; Turcotte & Schubert, 2014; Cramer et al., 2019). Many geophysical and geochemical processes are related to subduction zones, such as hydration of the mantle wedge and associated melt generation related to arc magmatism (e.g. Plümper et al., 2016), major earthquakes observed at different depths in the subducting slab and at megathrusts (e.g. Youngs et al., 1997), water transport in subducting slabs along faults (e.g. Faccenda et al., 2009) or the generation of petit-spot volcanoes, which might be associated with plate flexure around subduction zones (Hirano et al., 2006; Yamamoto et al., 2014). However, many of these processes are still incompletely understood. Processes inside and around subducting plates are, to a larger or smaller extent, controlled by the magnitude and the type of stress (extensive, compressive or shear) and by the dominant deformation mechanism (elastic, frictional-plastic or viscous). Since it is not possible to study stress and deformation mechanisms around subduction zones *in situ*, indirect approaches like geophysical imaging (e.g. Kearey et al., 2009) and numerical modelling in two-dimensions (2D) (e.g. Gurnis et al., 2004; Yamato et al., 2007; Schmeling et al., 2008; Gerya, 2011) and 3D (e.g. Schellart et al., 2007; Yamato et al., 2009;

Duretz et al., 2014) are frequently used to study subduction systems. Numerical models are suitable to quantify the magnitude of stress and the associated distribution of deformation mechanisms for subduction systems (e.g. Čížková et al., 2007; Garel et al., 2014). A better understanding of the magnitude of stress, their distribution and their associated dominant deformation mechanisms in subduction systems might ultimately help us to understand subduction-related geophysical and geochemical processes.

The main aim of this study is to quantify stresses and to determine the distribution of stress and dominant deformation mechanism around flexural regions in a subducting plate. Although there are numerous studies of numerical subduction simulations, only few numerical models quantified the distribution of stress (e.g. Hassani et al., 1997; Funiciello et al., 2003; Sobolev et al., 2006; Čížková et al., 2007; Babeyko & Sobolev, 2008; Farrington et al., 2014; Holt et al., 2015) and deformation mechanisms (e.g. Čížková et al., 2007; Garel et al., 2014). Like all models, they have limitations in their hypotheses, such as neglecting elastic deformation (e.g. Čížková et al., 2007; Chertova et al., 2012; Garel et al., 2014; Holt et al., 2015), no or only one creep deformation mechanism (e.g. Hassani et al., 1997; Funiciello et al., 2003; Farrington et al., 2014), a prescribed slab geometry (e.g. Sobolev et al., 2006; Babeyko & Sobolev, 2008), no free surface boundary condition (e.g. Čížková et al., 2007; Holt et al., 2015) or a yield stress being a function of depth only (e.g. Čížková et al., 2007; Garel et al., 2014) and not a function of the total pressure (negative mean stress). Here, we build on the above mentioned models, but without the mentioned limitations with the aim to make a step further in calculating stress and dominant deformation mechanisms at subduction systems. We apply a high-resolution (1 km grid spacing) 2D thermo-mechanical numerical model of the lithosphere-asthenosphere system and we consider five deformation mechanisms: elastic, frictional-plastic (Mohr-Coulomb criterion), diffusion creep, dislocation creep and Peierls creep. We apply a local iteration strategy to correctly calculate the partitioning of the strain rate between these five deformation mechanisms, because calculations without such iterations overestimate the calculated stress (Schmalholz & Duretz, 2017). Furthermore,

we consider two subduction scenarios, which represent two end-member conditions with respect to the forces driving subduction: (1) forced subduction whereby the subducting plate is pushed by far-field horizontal velocity (e.g., by ridge push), and (2) free subduction whereby subduction is driven only by the negative buoyancy of the subducting plate itself (slab pull). We initiate free subduction by forced subduction but set the far-field velocity to zero once slab pull is large enough to drive free subduction. We quantify the required minimum slab pull force to drive free subduction for our model configuration. We also quantify along-profile variations of gravitational potential energy (e.g., Molnar & Lyon-Caen, 1988; Molnar et al., 1993; Schmalholz et al., 2014; Schmalholz et al., 2019) across the subduction system, because these GPE variations cause horizontal forces and, hence, stresses. We also investigate whether differentiating criteria between forced and free subduction exist and what these criteria are. Furthermore, we evaluate the impact of elasticity and yield stress on the deformation and stress field around subduction zones. We do not configure our model to fit a particular subduction system, but in order to evaluate whether the modelled subductions are applicable to natural subduction zones, we finally compare the modelled topography and gravity anomalies with natural data from the Mariana subduction zone, which is a type-example for an ocean-ocean subduction system and has often been used for comparison with theoretical models (e.g., Funicello et al., 2003; Turcotte & Schubert, 2014).

2. - Mathematical model

2.1 Governing equations for numerical simulations

We use the 2D thermo-mechanical code MDoodz, which is based on the finite difference and marker-in-cell method (e.g. Duretz et al. 2011b; Gerya, 2019). The steady-state force balance equation is

$$\frac{\partial \sigma_{ij}}{\partial x_j} + \rho g_i = 0 \quad (1)$$

121 where i and j run from 1 to 2, 1 indicates horizontal and 2 vertical dimension, σ_{ij} are the components
 122 of the total stress tensor, x_j represents the spatial coordinates, ρ is the density and $g_i = [0, -g]$ is the
 123 gravitational acceleration vector with g being the gravitational acceleration. The conservation of mass
 124 for incompressible material is

$$\frac{\partial v_i}{\partial x_i} = 0 \quad (2)$$

125 where v_i are the components of the velocity vector. The temperature evolution equation is

$$\rho c \frac{dT}{dt} = \frac{\partial}{\partial x_i} \left(k \frac{\partial T}{\partial x_i} \right) + H_D + H_R \quad (3)$$

126 where d/dt represents the total time derivative, c the specific heat, k the thermal conductivity, H_R the
 127 radiogenic heat production and H_D the heating due to viscous and plastic dissipative work (here we
 128 assume that all dissipative work is converted into heat, i.e., Taylor-Quinney coefficient is 1, since we
 129 do not model grain size reduction).

130 The density is calculated with the following equation of state:

$$\rho = \rho_0 [1 + \beta(P - P_0)] * [1 - \alpha(T - T_0)] \quad (4)$$

131 where ρ_0 is the reference density at a reference pressure P_0 and temperature T_0 , P is the pressure
 132 (negative mean stress), T is the temperature, α is the thermal expansion and β is the compressibility.
 133 The components of the total stress tensor are

$$\sigma_{ij} = -P\delta_{ij} + \tau_{ij} \quad (5)$$

134 where δ_{ij} is the Kronecker delta ($\delta_{ij} = 1$ when $i = j$ and $\delta_{ij} = 0$ when $i \neq j$) and τ_{ij} are the
 135 components of the deviatoric stress tensor. We consider a visco-elasto-plastic rheology described by
 136 a Maxwell model (Moresi et al., 2003; Popov & Sobolev, 2008):

$$\dot{\epsilon}_{ij} = \dot{\epsilon}_{ij}^{\text{vis}} + \dot{\epsilon}_{ij}^{\text{el}} + \dot{\epsilon}_{ij}^{\text{pl}} = \frac{1}{2\eta} \tau_{ij} + \frac{1}{2G} \frac{D\tau_{ij}}{Dt} + \dot{\gamma} \frac{\partial Q}{\partial \tau_{ij}} \quad (6)$$

137 where superscripts $\dot{\epsilon}_{ij}^{\text{vis}}$, $\dot{\epsilon}_{ij}^{\text{el}}$ and $\dot{\epsilon}_{ij}^{\text{pl}}$ indicate viscous, elastic and plastic deviatoric strain rate tensors,
 138 respectively. The quantity η represents the effective viscosity, G is the shear modulus, t is the time,

139 D/Dt indicates the objective time derivative (e.g., Schmalholz et al., 2001), Q is the plastic flow
140 potential and $\dot{\gamma}$ is a plastic multiplier rate.

141 Frictional-plastic yielding is described by a Drucker-Prager criterion with the yield stress, τ_{yield}

$$\tau_{\text{yield}} = C \cos(\Theta) + P \sin(\Theta) \quad (7)$$

142 where C is the cohesion and Θ is the angle of internal friction. The yield function, F , is expressed as

143 $F = \tau_{\text{II}} - \tau_{\text{yield}}$ and the plastic potential is formulated as $Q = \tau_{\text{II}}$, being the square root of the

144 second invariant of the deviatoric stress tensor. Plastic deformation occurs whenever $F \geq 0$. The

145 plastic multiplier rate is computed as $\dot{\gamma} = 2\dot{\varepsilon}_{\text{II}} - \frac{\tau_{\text{yield}} - \tau_{\text{II}}^{\text{old}}}{Gdt} + \frac{\tau_{\text{yield}}}{\eta}$ or simply $\dot{\gamma} = \frac{F}{\eta^{\text{ve}}}$, where $\eta^{\text{ve}} =$

146 $\left(\frac{1}{\eta} + \frac{1}{Gdt}\right)^{-1}$, τ_{ij}^{old} are advected and rotated stress components from the previous time step and dt

147 is the time step. Subsequently, the plastic strain rate tensor is evaluated as $\dot{\varepsilon}_{ij}^{\text{pl}} = \dot{\gamma} \frac{\partial Q}{\partial \tau_{ij}} = \dot{\gamma} \frac{\tau_{ij}}{2\tau_{\text{II}}}$. In

148 practice, the stress state is mapped back onto the yield surface by modifying the effective viscosity as:

$$\eta = \eta^{\text{pl}} = \frac{\tau_{\text{yield}}}{2\dot{\varepsilon}_{\text{II}}^{\text{eff}}} \quad (8)$$

149

150 where $\dot{\varepsilon}_{\text{II}}^{\text{eff}}$ is the square root of the second invariant of the effective strain rate tensor, defined as

$$\dot{\varepsilon}_{ij}^{\text{eff}} = \dot{\varepsilon}_{ij} + \frac{\tau_{ij}^{\text{old}}}{2Gdt} \quad (9)$$

151 The viscous deformation is a linear combination of flow laws for diffusion creep (Hirth & Kohlstedt,

152 2003), dislocation creep (Hirth & Kohlstedt, 2003) and Peierls creep (Kameyama et al., 1999):

$$\dot{\varepsilon}_{ij}^{\text{vis}} = \dot{\varepsilon}_{ij}^{\text{dif}} + \dot{\varepsilon}_{ij}^{\text{dis}} + \dot{\varepsilon}_{ij}^{\text{pei}} \quad (10)$$

153

154 Diffusion creep (i.e., linear creep) is given by

$$\dot{\varepsilon}_{ij}^{\text{dif}} = F_{\text{dif}} A_{\text{dif}} \tau_{ij}^{n_{\text{dif}}} d^{-m_{\text{dif}}} \exp\left(-\frac{E_{\text{dif}}^* + PV_{\text{dif}}^*}{RT}\right) \quad (11)$$

155 Dislocation creep (i.e., power law creep) is given by

$$\dot{\epsilon}_{ij}^{\text{dis}} = F_{\text{dis}} A_{\text{dis}} \tau_{ij}^{n_{\text{dis}}} d^{-m_{\text{dis}}} \exp\left(-\frac{E_{\text{dis}}^* + PV_{\text{dis}}^*}{RT}\right) \quad (12)$$

156 Peierls creep (i.e., low-temperature plasticity or exponential creep) is given by

$$\dot{\epsilon}_{ij}^{\text{pei}} = F_{\text{pei}} A_{\text{pei}} \exp\left[-\frac{E_{\text{pei}}}{RT} (1 - \gamma)^{n_{\text{pei}}}\right] \left(\frac{\tau_{ij}}{\gamma \sigma_{\text{pei}}}\right)^S \quad (13)$$

157 with

$$S = \frac{E_{\text{pei}}}{RT} (1 - \gamma)^{(n_{\text{pei}}-1)} n_{\text{pei}} \gamma \quad (14)$$

158 In the above flow laws, F is a transformation factor to transform flow laws fitted from rock
 159 deformation data to flow laws for tensor components (e.g., Schmalholz & Fletcher, 2011; Gerya, 2019),
 160 A is a material constant determined from laboratory measurements, n is the stress exponent, d is the
 161 grain size, m is the grain size exponent, E is the activation energy, V is the activation volume, R is the
 162 gas constant, γ is an adjustable constant (Kameyama et al., 1999) and σ_{pei} is the Peierls stress (see
 163 values in Table 1).

164 Due to the occurrence of non-Newtonian creep mechanisms, Equation (6) is generally non-linear. We
 165 thus employ a local iteration method (Popov & Sobolev, 2008; Schmalholz & Duretz, 2017) that ensures
 166 correct additive decomposition of the strain rate tensor and computation of stress tensor. The resulting
 167 effective viscosity for dissipative deformation mechanism is equal to the pseudo-harmonic mean of
 168 the viscosities of each dissipative deformation mechanism:

$$\eta = \left(\frac{1}{\eta^{\text{dis}}} + \frac{1}{\eta^{\text{dif}}} + \frac{1}{\eta^{\text{pei}}} + \frac{1}{\eta^{\text{pl}}} \right)^{-1} \quad (15)$$

169 where η^{dis} , η^{dif} , η^{pei} and η^{pl} are the effective viscosities calculated with the corresponding second
 170 invariant of strain rate tensor for each deformation mechanism for the viscous and the plastic
 171 deformations. In the performed simulations, we apply a minimum cut-off of the viscosity at 10^{19} Pa·s
 172 and a maximum cut-off at 10^{25} Pa·s, allowing for viscosities in the models with six orders of magnitude
 173 difference.

The applied method allows to calculate iteratively the individual strain rates of each deformation mechanism at a given temperature and total strain rate. Figures 1a-d shows the individual strain rates of each dissipative deformation mechanism, a) dislocation, b) diffusion, c) Peierls creep and d) frictional-plasticity in a temperature versus total strain rate space. We perform these calculations for a temperature range of 300°C to 1'800°C and a total strain rate ranging from 10^5 to 10^{-50} [1/s] assuming a constant pressure of 1 GPa. Several mechanisms can be active simultaneously (Fig. 1). For illustrative purposes, we apply here a stress of 500 MPa to indicate the limit between the frictional-plastic and viscous domains. In the 2D numerical simulations, the plastic yield stress is pressure-sensitive and varies in space and time. To visualize the dominant deformation mechanism, we compare at each point in the strain rate versus temperature domain the four individual strain rates and identify which mechanism provides the highest strain rate. The mechanism associated with the largest strain rate is the dominant mechanism, as shown in the dominant deformation mechanism map displayed in Figure 1e. Diffusion creep is the dominant mechanism at high temperatures for low strain rates (in orange). Dislocation creep is dominant at high temperatures and higher strain rates (in red). Peierls creep is dominant at low temperature and moderate strain rates (in dark blue) and the plastic domain is dominant at low temperature and high strain rates (in light blue).

2.2 Calculation of slab pull and gravitational potential energy

We quantify two types of forces around subduction zones, one resulting from slab pull force and one resulting from spatial variations of the gravitational potential energy.

We calculate the slab pull force (per unit length) through time with the following integral for a specific time step (approximated by a sum for the numerical calculation):

$$\vec{F}_{SP} = \int_{H_{sb}}^{H_{LAB}} \Delta \rho g dV \approx \sum \Delta \rho g dx dz n^{lith} \quad (16)$$

where $\Delta \rho$ is the density difference between the density at each point (either the density of the lithosphere or the density of the asthenosphere) and the reference density depth profile on the left

side of the model, and dx and dz are the numerical grid spacings, respectively. We calculate the slab pull only in the asthenosphere, between the bottom of the model (H_{sb}) and the initial depth of the lithosphere–asthenosphere boundary (H_{LAB}). We consider only numerical cells that include lithospheric material for the calculation of the slab pull force by using the integer n^{lith} , which is 1 for cells including lithospheric material and 0 otherwise.

The gravitational potential energy per unit area (GPE) corresponds to the depth-integrated lithostatic pressure P_L [N/m²], which is calculated as

$$P_L(x, z) = \int_z^{St(x)} \rho(x, z') g dz' \quad (17)$$

The GPE is then

$$GPE(x) = \int_{Sb}^{St(x)} P_L(x, z) dz + const \quad (18)$$

where $St(x)$ is the topography of the model which can vary in the horizontal (x) direction, z is the depth and Sb is the base of the model (for details see Schmalholz et al., 2014). To calculate the topography in our simulations, we apply a numerical algorithm, which includes an Eulerian-Lagrangian free surface implementation, which allows resolving topographic variations at the sub-grid level (Duretz et al., 2016).

The along-profile variation of GPE, ΔGPE , is calculated by subtracting a reference GPE value from all other values. We choose here the GPE value on the left model side as reference value. Along-profile variation of ΔGPE can be due to a horizontal variation of density or a variation of the topography. The ΔGPE provides an estimate for the horizontal driving force per unit length (e.g., Molnar & Lyon-Caen, 1988; Schmalholz et al., 2014; Schmalholz et al., 2019) in the subduction system associated to the density variation at depth due to subduction and to the associated spatial variation of topography. Regions with a negative ΔGPE are under compression and regions with a positive ΔGPE are under extension.

3. - Model configuration

3.1 Configuration of the thermo-mechanical models

The size of the model domain is 3200 km in width and 660 km in height with a numerical resolution of 1 km by 1 km, yielding 2.112 million cells. The time step is calculated according to a Courant criterion of 0.4 in the model. We fixed the initial thickness of the lithosphere to 80 km following the seismic study from Kawakatsu et al. (2009) which localized the lithosphere-asthenosphere boundary (LAB) at this depth for the Pacific lithosphere subducting below Japan. A 5 km thick layer of weak material (cohesion of $1 \cdot 10^6$ Pa and internal friction angle of 0° ; see Table 1) is placed on the top of the lithosphere to mimic weak hydrated crust (Crameri et al., 2012). The main aim of this modelling study is to quantify stresses and determine dominant deformation mechanisms in flexural lithospheric regions. Therefore, we apply a simple density and temperature model for the sub-lithospheric region. Initially, the temperature of the asthenospheric mantle (T_{ast}) is homogeneous and for simplicity fixed at 1450°C . For the temperature of the lithospheric mantle, we consider also for simplicity a linear gradient from 0°C at the surface to the temperature of the asthenospheric mantle (T_{ast}) at the LAB (80 km depth). The initiation of subduction was facilitated by prescribing an oblique weak zone with an initial thickness of 10 km in the horizontal middle of the model (Fig. 2b). The weak zone is characterized by a low plastic strength (see Equation 7 and Table 1) and has the same properties as the weak upper layer.

We use dry olivine for the viscous flow laws of the lithosphere and asthenosphere with the rheological parameters reported in Table 1 (Hirth & Kohlstedt, 2003; Goetze & Evans, 1979 regularized by Kameyama et al., 1999). We employ the dry olivine flow law because the weaker wet olivine is commonly too weak in numerical subduction models and does not generate a coherent slab, but rather generates the dripping of the mantle lithosphere (e.g., Burov, 2010).

We consider two end-member subduction configurations to compare the stress and deformation mechanism in forced and free subduction models. In the forced subduction model, subduction is driven

by a horizontal velocity acting at the sides of the lithosphere. Therefore, the slab velocity is controlled by the applied boundary velocity. In contrast, subduction is only driven by the negative buoyancy of the dense lithosphere in a free subduction model. Therefore, the slab velocity can evolve freely and is controlled by the interaction of buoyancy, flexural and viscous resistance stresses in and around the slab. In the forced subduction model, we apply a symmetrical horizontal velocity on the lithosphere at both sides of the model (Fig. 2b). We choose symmetrical boundary conditions (Chertova, 2012) to have a straight slab as imaged in Japan with tomography (Liu & Zhao, 2016). The total convergence velocity is $10 \text{ cm}\cdot\text{yr}^{-1}$, as observed in Japan for the Pacific plate (Gripp & Gordon, 1990). These velocity profiles are implemented by specifying a material in-flux in the top part of the model sides until a depth of twice the thickness of the lithosphere. To ensure conservation of the mass, an equivalent out-flux is applied in the lower part of the model sides (Fig. 2b). For the boundary conditions, we use free slip at the model bottom and specific velocity profiles at the left and right model sides (Fig. 2b). At the top of the crust we use a free surface boundary condition (Duretz et al., 2016; Fig. 2b), because previous numerical studies show that the surface topography is controlled by the geometry, rheology and density of the slab (e.g. Zhong & Gurnis, 1994) and that a free surface condition is required to calculate realistic stresses in subducting slabs (Crameri et al., 2017).

For our model configuration (Fig. 2b), subduction will not initiate without horizontal boundary velocities, because there is initially no slab and, hence, no slab pull. Therefore, we initiate subduction in all the simulations with a weak zone in the lithosphere and with external velocities compressing the lithosphere (e.g. Toth & Gurnis, 1998). This model scenario is comparable to the compression-induced mode according to the classification of subduction initiation modes of Stern & Gerya (2018). To initiate free subduction, we first impose boundary velocities and then set the boundary velocities to zero once the slab is large enough to drive subduction without imposed boundary velocities. To constrain the moment when slab pull forces are sufficient to drive subduction, we perform several simulations in which we set the boundary velocities to zero after different simulation times (Fig. 2c), implying the

absence of material flux across lateral boundaries. We also include a weak domain (30 km thick) adjacent to right model boundary, which decouples the lithosphere from the lateral boundary and avoids prescribing a slab-retreat dominated subduction (Fig. 2c). To determine the conditions required for free subduction development, we start the model with forced subduction, save the configuration at different times (Fig. 2a) and then use the saved configurations in the free subduction model to evaluate whether subduction continues or not.

To test the impact of the applied boundary conditions, we also performed two simulations with different boundary conditions: one forced subduction simulation for which the horizontal velocity is only applied at the right model side and one free subduction simulation for which we add a weak zone at both lateral model sides. An overview of the performed simulations is given in Table 2.

3.2 Configuration for the gravity anomaly calculations

With the simulation results we also compute synthetic gravity anomalies in order to compare them with real data, in particular across the Mariana trench. For the gravity anomaly calculations, we use the algorithm of Won & Bevis (1987), based on the method of Talwani et al. (1959). The calculation uses the model geometry and corresponding density field of the numerical mesh at the final time step. To avoid edge effects, the model sides have been extended to great distances (10'000 km each side), which ensures the far-field fit of the gravity field. The topography in our model corresponds to the seafloor, therefore, we add a water layer of 5 km thickness with respect to the far-field, undeformed seafloor with a density of $1'000 \text{ kg}\cdot\text{m}^{-3}$. We then calculate the gravity contribution of all numerical elements at virtual measurement stations (10 km spacing) at sea-level to obtain a synthetic free-air anomaly profile, which can be then compared to the anomaly profile obtained from natural data.

4. - Results

We performed nine simulations whose characteristics and differences are listed in Table 2. We employed the colour-maps “lapaz” and “vik” of Crameri (2018) for the visualization.

4.1. - Quantification of slab pull force and gravitational potential energy

We first compare three different simulations (Fig. 3) using identical material parameters, namely simulation S0 for forced subduction scenario (Figs. 3a-c) and simulations S1 and S2 for free subduction scenarios (Figs. 3d-i). The only difference between S1 and S2 is the time at which we set the horizontal boundary velocities to zero. The time at which free subduction starts is termed t_{free} and it is equal to 1.25 Ma in S1 and 1.17 Ma in S2. In S0 (Figs. 3a-c), subduction develops with a relative retreat of the trench to the right of the model. This retreat is caused by the velocity imposed on the left side of the box. This trench retreat is not observed in S1 and S2 because no more lithosphere is created on the left side of the box due to the change of boundary conditions (Figs. 3d-i). The evolution of slab geometry differs between models S0 and S1. At the beginning of the simulations (Figs. 3a and d) slabs are similar in both models. The time of these two panels (Figs. 3a and d) is not identical because for S1 we display the first time step of the free subduction simulation, which has a different numerical time step (due to the Courant criterion which is velocity dependent) than the forced subduction simulation. With progressive time, the dip and curvature of the slabs evolve differently. S0 shows a more straight and vertical slab with a smaller curvature in the deeper regions, while S1 shows a slab dip in the opposite direction than the one in the shallower region (Fig. 3f). This curl-type motion is associated with the configuration of the free subduction model, which requires the asthenospheric material to fill the region of the detached slab at the top right region of the model.

Figures 3g-i shows a scenario of a failed model of free subduction development (S2). The only difference between S1 and S2 is the time at which the horizontal boundary velocities are set to zero (t_{free}). These simulations show that the difference between a successful or failed free subduction simulation is linked to the slab pull force, associated only to the negative buoyancy of the slab after

317 t_{free} . To determine the slab pull force required to develop a free subduction in our model configuration
 318 and to evaluate the impact of rheological parameters, we first calculate the slab pull force for three
 319 different forced subduction simulations (Fig. 4b), namely S0, S4 and S5 (Table 2). In S4 we increased
 320 the shear modulus to $G = 3 \cdot 10^{13}$ Pa, in order to decrease the impact of elasticity, and in S5 we reduced
 321 the friction angle to 5° . The three simulations show a similar increase of the slab pull force as function
 322 of time up to ca. 4 Ma (Fig. 4b). After 4 Ma, S5 differs from the other two simulations and shows a
 323 larger slab pull for the same time. We apply several free subduction starting times (t_{free} corresponding
 324 to squares and circles in Fig. 4a) for the reference forced subduction simulation S0 in order to evaluate
 325 the required slab pull force for free subduction (Fig. 4a). For the applied model configuration, a slab
 326 pull force larger than $1.8 \text{ TN} \cdot \text{m}^{-1}$ is required to develop a free subduction in the case of S0. The time to
 327 generate this slab pull force in S0 is ca. 1.15 Ma using a horizontal boundary velocity of $5 \text{ cm} \cdot \text{yr}^{-1}$ at
 328 each side of the model. If the slab pull is not large enough before the horizontal boundary velocities
 329 are set to zero, then the subduction slows down and ceases, temperature conduction heats up the
 330 slab, as illustrated by the shift of the isotherm for $1'440^\circ\text{C}$ in the asthenosphere (Fig. 3h), and the base
 331 of the lithosphere starts to delaminate. In contrast, when slab pull is larger than $1.9 \text{ TN} \cdot \text{m}^{-1}$ in S0, the
 332 subduction continues. The vertical velocities associated with the delamination for a failed free
 333 subduction model are significantly slower than velocities of the subducting slab (compare times in Figs.
 334 3c, f and i).

335 The quantification of along-profile variations of GPE, ΔGPE , in the lithosphere–asthenosphere system
 336 allows quantifying the along-profile variation of horizontal driving forces in the system. Hence, regions
 337 under overall horizontal compression or extension are identified and the corresponding horizontal
 338 forces are quantified. To investigate these forces around the modelled subduction system, we quantify
 339 the relative contribution of (i) density variations below the initial lithospheric thickness due to
 340 subduction and (ii) topography variations due to lithospheric flexure to ΔGPE . To quantify
 341 contributions due to sub-lithospheric density variations we calculate ΔGPE by integrating P_L from the

model bottom up to a depth of 80 km, the initial lithosphere thickness. The relative variation of the total ΔGPE and the topography agree in the right side of the subduction trench for both forced and free subduction model (Figs. 5 and 6). This agreement indicates that the variation of total ΔGPE is controlled by the variation of topography created by the flexure of the lithosphere, and that the flexure of the subducting plate does not affect the density field below the lithosphere. In contrast, relative variations of total ΔGPE and the topography on the upper plate side of the trench do not agree. If a significant slab has developed, then the variation of total ΔGPE on the upper plate side of the trench agrees with the ΔGPE beneath 80 km because the variation in total ΔGPE is there controlled by deep density variations due to subduction of the cold slab. The GPE calculation shows that the subduction system is characterized by three regions with respect to ΔGPE variations and associated horizontal driving forces: (1) extensional horizontal driving forces related to the flexural bulge of the subducting plate, (2) compressive horizontal driving forces in the trench region associated to the negative topography of the trench region and (3) extensional horizontal driving forces in the overriding plate region related to deep density variations caused by the subducted plate (Figs. 5 and 6). The maximal difference in total GPE for the forced subduction is ca. 80 TN/m and for the free subduction ca. 110 TN·m⁻¹ (Fig. 5c and 6c). The division of these values by the model height of 660 km provides a minimum estimate for the vertical average of the horizontal differential stress caused by subduction-related variations of GPE. These vertically-averaged horizontal differential stresses are ca. 121 MPa and 167 MPa for the forced and free subduction, respectively. These vertically-averaged differential stresses are required to maintain the subduction zone and to avoid that the subduction system disappears immediately and returns to a state of static equilibrium, which is characterised by vertical density variations only and no topography.

4.2. - Analyses of strain rate, deformation mechanisms, effective viscosity and horizontal deviatoric stress

Strain rate

We quantify the strain rate field with the square root of the second invariant of the deviatoric strain rate tensor, $\dot{\epsilon}_{II}$, for the forced (Figs. 7a-c, S0) and the free subduction model (Figs. 7d-f, S1). High values of $\dot{\epsilon}_{II}$ indicate regions of intense deformation whereas low values indicate regions of little deformation. The distribution and magnitude of $\dot{\epsilon}_{II}$, hence, indicates, for example, whether the deformation around a subduction system and within the slab is either more or less homogeneous or strongly heterogeneous. For both S0 and S1 the strain rates in the upper region of the lithosphere are small away from the subduction zone (Fig. 7). These low strain rate regions feature high viscosity, dominantly elastic deformation (see following sections, Figs. 9 and 10) and an essentially rigid, plate-like behaviour. In S0, strain rates are generally highest in the lower region of the lithosphere and in the upper regions of the asthenosphere (Figs. 7a-c). These high strain rates are due to the applied horizontal boundary velocity profile, which move material into the model domain in the upper model region and, to conserve mass, move material out of the model in the lower regions (see Fig. 2b). For S1, the strain rates in the upper plate region, in the front of the subducting slab, are significantly smaller because no material in- and out-flow is considered (Figs 7d-f). However, strain rates are also high in the lower regions of the subducting plate (right model region) where the underlying asthenosphere is being sheared by the subducting plate (Figs. 7d-f).

Deformation mechanisms

To study the relative importance of the five modelled deformation mechanisms, namely elastic deformation, frictional-plastic deformation, diffusion creep, dislocation creep, and Peierls creep we plot the individual strain rates for each deformation mechanism separately using Equation (6) (Fig. 8). Figure 8a shows the total strain rate corresponding to the results shown in Figure 7c for S0. Strain rates due to elastic deformation are significant in the upper regions of the lithosphere in the subduction

zone (Fig. 8b). Strain rates due to frictional-plastic deformation are significant (i) in the weak zone between the overriding and subducting plate and (ii) in the uppermost region of the subducting plate where the plate starts to subduct (Fig. 8c). This region corresponds to the outer hinge zone of the subducting plate. In the lower region of the lithosphere and upper region of the asthenosphere, both diffusion and dislocation creep are significant (Figs. 8d and e). Strain rates due to dislocation creep are generally higher than the ones for diffusion creep. High strain rates due to dislocation creep are in the mantle lithosphere and in the mantle wedge corner (Fig. 8e). Strain rates caused by Peierls creep are significant only (i) in small areas in the region where the plate subducts and (ii) in a small area around the hinge region of the subducting plate (Fig. 8f). Around the subduction zone, each of the five deformation mechanisms is dominant in some region (Fig. 8g). Therefore, all five deformation mechanisms are important for lithosphere deformation around the subduction zone. For comparison, the corresponding effective viscosity field is also shown (Fig. 8h). Upper regions of the lithosphere with high effective viscosity correspond generally to regions in which elastic deformation is dominant. Low viscosity regions correspond to regions in which dislocation and diffusion creep is dominant.

Considering the entire model domain, the distribution of dominant deformation mechanism is similar for S0 and S1 (Fig. 9) except for dislocation creep. The deformation associated with dislocation creep corresponds to the region with the highest strain rate in Fig. 7. Frictional-plastic deformation is dominant in three different regions: in a thin zone (ca. 5 km thick) on the top of the lithosphere corresponding to the model weak crust, in the triangular weak zone mimicking an accretionary prism between the subducting and overriding plates, and in the outer hinge zone caused by flexure of the downgoing slab. In this hinge zone, frictional-plastic deformation associated with the development of normal-fault-type shear zones propagates downwards to ca. 30 km depth. Elastic deformation is dominant in the upper regions of the lithosphere down to a depth of ca. 60 km, measured orthogonally from the top of the lithosphere. Elastic deformation is dominant in the subducting slab to depths of more than 500 km (Figs 9c and f).

415

416 Effective viscosity

417 The effective viscosity has contributions from all the considered viscous and plastic deformation
418 mechanisms and thus depends on the strain rate, temperature and pressure. Since these quantities
419 vary in space and time, it is not trivial to predict lithospheric regions, which are mechanically strong or
420 weak, or to predict the absolute values of the effective viscosity. In our simulations, the effective
421 viscosity varies by six orders of magnitude (Fig. 10). The viscosity below the lithosphere, in regions
422 unaffected by the subducted slab, exhibits an increase as function of increasing pressure with depth.
423 This increase from ca. 10^{19} to 10^{22} Pa·s at the base of the model is due to the increase of pressure with
424 depth controlled by the activation volume, V (Table 1). Overall, the effective viscosity distribution is
425 similar for S0 and S1.

426

427 Horizontal deviatoric stress

428 To identify regions in horizontal compression or extension and to quantify stress magnitudes we
429 analyse the distribution of the horizontal deviatoric stress, τ_{xx} . The bending of the slab around the
430 subduction zone causes flexural stresses and this bending also generates a topographic high, the so-
431 called flexural fore-bulge, in the slab region in front of the subduction zone (e.g., Turcotte and
432 Schubert, 2014). Therefore, we also analyse in the following this topographic bulge to assess how much
433 topographic variation is associated with the calculated stress distribution and magnitudes. The link
434 between surface topography and rheological behaviour of the subducting slab has been also
435 demonstrated by previous studies (e.g., Zhong & Gurnis, 1994; Crameri et al., 2017). Absolute values
436 of τ_{xx} are largest in the upper part of the lithosphere where the subducting lithosphere is bending and
437 is colder (Fig. 11). During the initial stages of subduction, both S0 and S1 show the characteristic
438 pattern of bending (e.g. Burov, 2011; his figure 5), or flexure, around the hinge zone of the subducting
439 plate (Figs. 11a and d). The outer hinge region is under extension (positive τ_{xx}) and the inner hinge

region is under compression (negative τ_{xx}). When subduction evolves and slabs become longer, the plate straightens back, or unbends, causing a stress pattern in the opposite sense (Figs. 11c and f; e.g. Faccenda et al., 2012): the upper part of the lithosphere is under compression and the lower part under extension.

In S0, the horizontal regions of the subducting plate are under compression during the initial stages of subduction (Fig. 11a). With progressive subduction, the stress state of the horizontal region changes from compression to extension and extensive values of τ_{xx} become larger with progressive subduction (Figs. 11b and c). This change in stress state is likely due to the increasing slab pull, which starts pulling the subducting plate once it is larger than the compressive stresses due to the applied boundary velocities. The orientation and magnitude of the principal stresses, σ_1 and σ_3 , confirm the result of distribution of τ_{xx} (Figs. 11g and h). If the horizontal regions of the lithosphere are in compression, then σ_1 is approximately horizontal (Fig. 11g). For extension, σ_3 is horizontal. The orientation of the principal stresses shows that these principal stresses are always either parallel or orthogonal to the local dip of the subducting plate so that the strong regions of the slab act as a stress guide (Figs. 11g and h).

Impact of elasticity

Rocks generally deform visco-elastically, and the time scale over which elastic stresses are relaxed can be estimated to the first order by the so-called Maxwell relaxation time, which is the ratio of the effective viscosity to the shear modulus, η/G . Using 10^{23} Pa·s as representative, average effective viscosity for the slab and $3 \cdot 10^{10}$ Pa for G provides a relaxation time of ca. 100 kyr. One could, therefore, argue that elastic stresses are largely relaxed during subduction processes with durations of several millions of years and that, hence, elasticity might not be important for slab deformation during subduction (e.g., Schmeling et al., 2008). To study the impact of elasticity in our models, we performed two forced subduction simulations: one with a shear modulus, G in Equation (6), which is two orders

of magnitude larger than in the reference simulation, i.e. $3 \cdot 10^{12}$ Pa, and one with a shear modulus, which is three orders of magnitude larger than in the reference simulation, i.e. $3 \cdot 10^{13}$ Pa (Fig. 12). In the simulations with unrealistically high shear modulus of $3 \cdot 10^{12}$ and $3 \cdot 10^{13}$ Pa the elastic behaviour is significantly less dominant because the Maxwell relaxation time, during which elastic stresses relax, is significantly shorter (e.g., Jaquet et al., 2016).

We compare the topography of the subducting plate from the three numerical simulations with the analytically calculated flexural geometry fitting the Mariana trench (Turcotte & Schubert, 2014) and obtain reasonable agreement (Fig. 12a). However, the height of the flexural bulge, ca. 800 m, is higher in the reference simulation than in the simulations with $G = 3 \cdot 10^{12}$ Pa and $G = 3 \cdot 10^{13}$ Pa, ca. 400 m. The lateral topographic variation around the bulge region is considerably smaller in the simulations with unrealistically high values of G , indicating that elasticity has a strong impact on the flexural behaviour in the bulge region. The depth of the trench is similar for the three simulations.

The overall distribution of the horizontal deviatoric stress, τ_{xx} , in the subducting plate is similar for the three simulations (Fig. 12 b to d). However, the absolute values of τ_{xx} are smallest for the reference simulation and the reduction of the impact of elasticity increases stress values (Figs. 12b-d). In the simulation with $G = 3 \cdot 10^{13}$ Pa, the overriding plate exhibits significant larger compressive stresses than in the simulation with a standard elastic shear modulus. The regions dominated by elastic deformation are replaced mostly by the frictional-plastic deformation mechanism when the impact of elasticity is reduced (Figs. 12e-g), except in the deeper regions of the subducting lithosphere where elastic deformation is replaced by Peierls creep (Figs. 12e-g). The results show that the implementation of elasticity significantly affects both the magnitude of stresses and the distribution of non-elastic deformation mechanisms.

Impact of friction angle

The absolute magnitudes of stress, especially maximal values, in the mantle lithosphere are still contentious. One reason for this is that different laboratory flow laws for mantle rocks predict stresses that can be up to one order of magnitude different for the same temperature, strain rate and pressure (e.g., Mei et al., 2010; Jain et al., 2017). Furthermore, different authors apply stress cut-offs in the mantle, for example, to match tectonic plate size distribution in mantle convection simulations (e.g., Mallard et al., 2016) or apply reduced friction angles ($\leq 15^\circ$), which further reduce with progressive plastic strain (down to 2°), in order to indirectly consider the weakening effects of fluids or other strain softening mechanisms (e.g., Erdős et al., 2014). Moreover, since the effective friction angle depends on fluid pressure, the appropriate friction angle for the mantle lithosphere is debated and, hence, different friction angles are often used for the mantle lithosphere in numerical models of subduction (e.g., Li et al., 2010). To test the impact of absolute stress magnitudes, we performed two more simulations with a reduced friction angle for the lithosphere (Fig. 13). The friction angle is reduced to limit maximal stress values but not to mimic any particular natural process. The standard value for the friction angle is 30° and we decrease this angle to 5° (Figs. 13c and f) and 1° (Figs. 13d and g) in the two additional simulations. The reduction of friction angle changes the topographic profiles around the flexural bulge of the subducting plate (Fig. 13a). A friction angle to 5° generates a shorter flexural wavelength whereas a friction angle of 1° does not generate a realistic flexural topography at all. These results are in broad agreement with results of Crameri et al. (2017) who, amongst others, also show a larger bulge and flexural wavelength with larger friction angle (their figure S10).

The reduction of friction angles reduces, as expected, the maximal absolute values of τ_{xx} (Figs. 13b-d) and changes the distribution of dominant deformation mechanism (Figs. 13e-g). In the simulation with a friction angle of 1° a continued subduction cannot be established because the slab is thinned in the trench region and detaches, or breaks-off (Fig. 13g). The reduction of stress magnitudes makes the slab mechanically so weak that the slab pull force cannot be transmitted anymore to the horizontal

regions of the lithosphere, the slab pull cannot drive horizontal plate motion anymore so that the slab detaches. For a friction angle of 5° maximal absolute deviatoric stress magnitudes are between 50 and 100 MPa. Also, for a friction angle of 5° the region with dominant frictional-plastic deformation is significantly larger than for a friction angle of 30° (Fig. 13e and f). Particularly, the region of slab unbending (between 50 and 100 km depth and $200 \text{ km} < x < 250 \text{ km}$ in Fig. 13f) shows significant frictional-plastic deformation, which is not the case for a friction angle of 30° (between 50 and 100 km depth and $200 \text{ km} < x < 250 \text{ km}$ in Fig. 13e). Maximal absolute deviatoric stress magnitudes of a few hundred MPa seem to be required in order to generate a flexural wavelength corresponding to the Mariana trench, as is the case in the model with standard elastic shear modulus.

Impact of boundary conditions

We have also performed a forced subduction simulation (S7, Table 2) and a free subduction simulation (S8) using different boundary conditions than in reference models (S0, S1). In S7 we apply a horizontal velocity only at the right model side, but with a value of $10 \text{ cm}\cdot\text{yr}^{-1}$ so that the absolute convergence velocity is identical to the one of S0. After ca. 2.8 Ma the stress field and the slab geometry are similar for S0 and S7 (Fig. 14a and c). However, after ca. 4 Ma the slab geometry and, hence, the associated stress field are different (Fig. 14b and d). In S8 we apply a weak zone at both lateral model sides so that the slab and overriding plate can detach from both lateral model sides. After ca. 6.9 Ma and ca. 8 Ma both simulations S1 and S8 exhibit a similar slab geometry and stress field. These additional simulations indicate that the applied boundary conditions have a significant impact on the forced subduction simulations but not on the free subduction simulations.

5. – Discussion

The deformation behaviour, the thermal structure and the mineral composition of the lithosphere are only approximately known and, hence, published numerical subduction models commonly differ in

538 terms of the applied flow laws, temperature and density fields. Our models were not designed to
539 closely match a specific subduction system and we used standard rheological models, and simple
540 density and temperature fields. However, we assume that our mathematical model, the model
541 configuration, the applied boundary conditions, the temperature field, the densities and the applied
542 rheological model, including the different creep flow laws, generate a subduction process, which
543 should be comparable, to the first order, to a natural ocean-ocean subduction system. To test whether
544 the modelled effective deformation behaviour, such as flexure of the slab, and the modelled slab pull,
545 controlled by the model density field, are indeed in broad agreement with natural observations, we
546 compare our model results with a major subduction system, namely with real data from the Mariana
547 subduction zone. We chose the Mariana trench because it is a prominent subduction zone and has
548 been frequently used for the comparison with mathematical subduction models (e.g., Funiciello et al.,
549 2003; Turcotte & Schubert, 2014). We first compare topography of the ocean floor to assess the
550 flexural behaviour of the lithosphere. Secondly, we compare modelled gravity anomalies with
551 anomalies derived from data measured in the field in order to assess the density field (Figs. 15 and 16).
552 For the topography comparison, we use the seafloor topography data from the Mariana trench
553 (Funiciello et al., 2003; Turcotte & Schubert, 2014). For the visual comparison between natural and
554 calculated topography profiles, we have used the position of the trench ($x = 0$) as a reference (Fig. 15).
555 The first-order topography of both forced and free subduction models fits the natural topography and
556 the analytical solution of Turcotte & Schubert (2014). Therefore, the applied flow laws and rheological
557 behaviour of our model lithosphere, controlling the height of the flexural bulge and the flexural
558 wavelength, broadly agree with the flexural behaviour of a natural oceanic lithosphere.
559 For the gravimetric comparison, we use the global WGM2012 model for free-air gravity anomaly,
560 which has a resolution of $2' \times 2'$ (Bonvalot et al., 2012), and compare it with the synthetic free-air gravity
561 anomalies calculated for our model density field (Fig. 16). We extract ten gravity anomaly profiles
562 perpendicular to the trench from the WGM2012 (Fig. 16a). From the numerical models, we calculate

563 two free-air anomaly profiles, one for the forced and one for the free subduction model (Fig. 16b). For
564 comparison, we have co-located all gravity anomaly profiles at the trench (Fig. 16b). Our modelled
565 free-air gravity anomalies agree with the long-wavelength variation of the observed anomaly.
566 Modelled anomalies exhibit a similar width and amplitude in their spatial variation compared with the
567 natural free-air gravity anomalies. The shorter wavelength variations and peaks in the natural gravity
568 anomalies are due to the natural seafloor topography, reflecting the formation and deformation of the
569 volcanic arc to the West of the Mariana trench and the seamounts to the East on the Pacific plate (Fig.
570 16a). These peaks vary across the selected 10 observed profiles and our model has not aimed at
571 reproducing such short wavelength variations.

572 The comparison of model and natural topography allows evaluating the applicability of the modelled
573 flexural behaviour of the lithosphere to nature. This modelled flexural behaviour and the associated
574 topography is controlled by the considered deformation mechanisms, the flow laws and material
575 parameters (e.g. Zhong & Gurnis, 1994; Crameri et al., 2017). Consequently, the topography
576 comparison allows evaluating whether the employed flow laws and material parameters are applicable
577 to natural cases. However, since natural topography can vary significantly between different
578 subduction zones, different subduction zones likely exhibit different rheological and density
579 characteristics (e.g., Crameri et al., 2019). The free surface implementation is therefore, well suited for
580 the comparison of model and natural topography. A modelled free surface topography is also essential
581 for the calculation of along-profile variations of ΔGPE (Figs. 5 and 6). The topography controls gravity
582 anomalies, which further depend on the density field. We calculate the density with an equation of
583 state (EOS), which depends on T and P (see Equation 4). We do not consider mineral phase
584 transformation, which could affect the localization of deformation in this compressive setting (e.g.,
585 Hetényi et al., 2011). The comparison of gravity anomaly profiles from our model with natural free-air
586 gravity anomaly profiles obtained across the Mariana trench shows that both of our model density
587 fields are appropriate; at least for the considered natural subduction zone (Fig. 16). Our simulations

show differences in the forced and free subduction models. However, with respect to topography (e.g., bulge) or gravity anomalies, these differences are not significant (Figs. 15 and 16). The maximal amplitude of the modelled gravity anomaly profile for the free subduction model is larger than the one for the forced subduction model. However, considering the lateral variability of natural gravity anomaly profiles across the Mariana trench, both models fit the natural data to a good level. Alternative to gravity anomalies, ΔGPE profiles show larger differences between forced and free subduction models, because for a more vertical slab the ΔGPE anomaly is narrower (Figs. 5 and 6).

The calculated stress field (Fig. 11) shows that the subducting plate's outer bend of the hinge zone is under extension and the inner bend is under compression. This deformation distribution is expected for the subducting plate, but our model allows quantifying the contribution of individual deformation mechanism. The flexural behaviour varies along the subducting plate and in the downgoing plate the outer region of the plate is under compression and the inner one under extension (Fig. 11). This variation of flexural behaviour along the subducting slab is in agreement with analytical results of Ribe (2010) who shows that the sign of the rate of curvature changes along the slab. Ribe (2010) considered a simpler, linear viscous behaviour of the slab. The comparison with our results, considering five deformation mechanisms and temperature dependent flow laws, indicates that a linear viscous model can capture the first order flexural behaviour of a subducting slab. Regions with high compressive deviatoric stresses of several hundreds of MPa in the downgoing slab next to the subduction interface (Figs 11c and f) can be important for the interpretation of exhumed (ultra-)high pressure rocks. Subducted crustal rock units in the outer regions of subducting slabs could experience high stress and, hence, tectonic overpressure (e.g., Schmalholz & Podladchikov, 2013; Moulas et al., 2019) before they are detached from the subducting plate and return to the surface. If the stress and, hence, the internal resistance of the slab is reduced, then a continuous subduction is not possible anymore because the slab detaches, and the slab pull force cannot be transferred anymore to the horizontal region of the

lithospheric plate (Figs. 13d and g). This behaviour is consistent with the “shallow breakoff” of Duretz et al. (2011a), which systematically occurred for weak slabs (young plates). This result agrees also with predictions of the analytical model of Ribe (2010) who shows that the subduction velocity approaches the Stokes velocity of a detached object when the internal resistance of the slab becomes smaller than the external resistance of the material surrounding the slab.

Stress magnitude and distribution in subducting plates are one of the controlling parameters of intra-slab processes such as earthquakes, metamorphism or fluid transfer. Our results show that in a subducting lithosphere all five considered deformation mechanisms are active and contribute to shape the total stress field (Fig. 8). Particularly, our results show that elastic deformation is the dominant deformation behaviour in large regions of the subducted slab (Fig. 8g). Therefore, models aiming to calculate the intra-plate stress field and intra-plate processes should consider the impact of elastic deformation on the stress field.

Our model results can contribute to a better understanding of the development of faults during plate flexure, and its importance for the hydration of the subducting plate. Several mechanisms have been proposed to bring water from the surface into the mantle, such as bending-related faulting (e.g., Ranero et al., 2003; Faccenda et al., 2008; Faccenda et al., 2009), thermal cracking (Korenaga, 2017) or seismic pumping (Sibson et al., 1975). The length and distribution of faults, which could develop by plate flexure, is therefore important to assess the water budget of the subducting plate. Furthermore, Peacock (2001) suggested that dehydration of antigorite (serpentine) by dehydration reactions could be an explanation for intermediate-depth earthquakes. To constrain the depth of faulting, and therefore the maximum depth where water could be added to the subducting plate is fundamental to test whether part of the earthquakes observed between 15 to 25 km depth could be explained by metamorphic dehydration reaction or not (Peacock, 2001). Our model predicts the formation of faults

in the outer hinge zone of the subducting plate (Figs. 8g and 9). These faults develop in a zone of ca. 100 km width around the bulge. These frictional-plastic faults reach a depth of ca. 40 km. However, the spatial extent of faulting is highly dependent on the elasticity and plasticity parameters in the model. Figure 12 shows that the extent of plastic deformation changes drastically if the elastic deformation behaviour is modified.

Flexure of the subducting plate has been also proposed as an important mechanism for the formation of petit-spot volcanoes (Hirano et al., 2006). Petit-spot volcanoes represent small volumes of alkaline magmas that have been emitted on the top of the downgoing Pacific plate in front of Japan (Hirano et al., 2006). These magmas are emitted 300 to 600 km away from the trench, which could correspond to the region where the plate starts to bend (Hirano et al., 2006). Petit-spot volcanoes are, therefore, interpreted as the products of deformation-driven melt segregation of melt initially present at the base of the lithosphere. Since their first observation in front of Japan, petit-spot volcanoes have been identified in several subduction zone, such as Tonga (Hirano et al., 2008), Chile (Hirano et al., 2013), and Sunda trenches (Taneja et al., 2015), or as an accreted petit-spot in Costa Rica (Buchs et al., 2013). These observations suggest that petit-spot volcanism is a global process around subduction zones. In this context, the deformation behaviour and its changes along the lithosphere-asthenosphere boundary are critical to understand how low degrees of volatile rich melts can be extracted from the base of the lithosphere. Earlier models suggest that large flexural curvatures imposed on the pre-flexed lithosphere might instigate brittle fracturing even at the base of the lithosphere (Hirano et al., 2006; Yamamoto et al., 2014). Our Figure 8g shows, however, that deformation around the base of the lithosphere (from 50 km depth to the LAB) is likely controlled by diffusion and dislocation creep. Propagation of brittle faults down to the base of the lithosphere is, therefore, unlikely. Consequently, percolation of melts within the basal viscous region of the lithosphere, before its extraction by faults when the melts reach the elastic domain, seems a more realistic model for petit-spot formation. A

possible mechanism of melt transport in the viscous region could be ascent in the form of porosity waves (e.g., Connolly & Podladchikov, 2007). The viscous percolation model is in agreement with recent multiple saturation laboratory experiments which show that petit-spot melts equilibrate last with the mantle phases (olivine, orthopyroxene, and clinopyroxene) at pressures between 1.8 and 2.1 GPa and at temperatures around 1'280–1'290°C, which are P-T conditions corresponding to the lithosphere rather than the top of the asthenosphere (Machida et al., 2017). Another argument in favour for the ascent and equilibration of low degree melts at the base of the lithosphere is the presence in petit-spot lavas with xenoliths showing evidence of metasomatic enrichment (Pilet et al., 2016). One important question concerning petit-spot formation is which process or parameter initiates melt percolation in the basal part of the lithosphere. The porosity at the base of the lithosphere is frequently considered as too small to allow for silicate melt percolation. Our numerical model allows quantifying the extension produced by plate flexure. Figure 11 suggests that the base of the lithosphere where the plate starts to bend is slightly in extension, but the effect is very limited at depths greater than 50 km where absolute magnitudes of τ_{xx} are significantly less than 10 MPa. Nevertheless, the current model considers a homogeneous dry-olivine lithology and future models considering additionally wet or higher-porosity domains at the base of the lithosphere, i.e., in the low seismic velocity zone, will be important to constrain the effect of plate flexure on the stress state at the base of the lithosphere.

6. - Conclusions

We performed 2D thermo-mechanical numerical simulations of subduction, considering both forced and free subduction regimes as well as a composite rheological model including elasticity, frictional-plasticity, diffusion, dislocation and Peierls creep. In the forced subduction regime, we initiate subduction by applying horizontal boundary velocities. The initiation by a forced subduction must generate an embryonic slab to continue a free subduction simulation, for which boundary velocities

688 are set to zero and subduction is driven by buoyancy forces of the slab. For our configuration, the
689 embryonic slab should produce a slab pull force (per unit length) of at least $1.8 \text{ TN}\cdot\text{m}^{-1}$ so that free
690 subduction can occur.

691 We show that the five employed deformation mechanisms are all important for the evolution of the
692 subducting lithospheric plate for both forced and free subduction. Particularly, elastic deformation is
693 important because it affects the flexural behaviour, the magnitude and distribution of deviatoric
694 stresses and the distribution of dominant deformation mechanisms. Simulations with an unrealistic,
695 reduced impact of elasticity show significantly larger stress magnitudes and larger regions with high
696 stresses in the subducting and overriding plate than corresponding simulations with appropriate
697 elasticity. For our model configuration, the simulations with elasticity also fit best the natural flexural
698 bulge and wavelength of the Mariana subduction zone. Therefore, including elasticity in numerical
699 subduction models seems important for an appropriate calculation of stresses, of the distribution of
700 deformation mechanisms and of flexure in a subduction system.

701 We also show that a subduction system generates along-profile variations of GPE corresponding to
702 horizontal driving forces in the lithosphere-asthenosphere system. These GPE variations result from
703 either topography variations associated to plate flexure or from deeper density variations caused by
704 subduction of the lithosphere into the asthenosphere. For both forced and free subduction models the
705 GPE variations cause compressive forces in the trench region and extensive forces in front and behind
706 the trench region. These latter likely have strong impact on driving petrological processes such as melt
707 migration across the lithosphere, at significant distance from the trench.

708 Although our models were not specifically designed for reproducing a particular subduction zone, the
709 simulation results closely match natural seafloor topography and free-air gravity anomalies across the
710 Mariana trench. This fit indicates that our model density field and the applied rheological model
711 generate buoyancy and flexural stresses in agreement with this particular natural subduction zone.
712 Calculated maximal absolute values of deviatoric stresses in the bending and subducting lithosphere

are approximately 500 MPa. If absolute magnitudes of maximal deviatoric stresses are significantly less than 100 MPa, caused for example by a reduced friction angle, continuation of subduction does not occur because the denser subducting slab detaches from the lithosphere. Hence, deviatoric stress magnitudes of several hundreds of MPa are required for a continuous subduction. The uppermost region of the oblique, subducting slab shows high compressive stress, due to unbending, directly next to the subduction interface. Such high compressive stress may affect metamorphic reactions in rock units before they are detached from the subducting slab and exhumed to the surface.

Figure 1. Individual strain rates of dissipative deformation mechanisms for (a) dislocation creep, (b) diffusion creep, (c) Peierls creep and (d) plastic deformation as function of temperature and total strain rate for the applied rheology of the mantle. In panels (a-d), the highest individual strain rates for each deformation mechanism are shown in dark blue, while the slower are in light beige. Calculations made at a pressure of 1 GPa with a grain size of 5 mm. The panel (e) shows the corresponding dominant deformation mechanism map as identified by the legend. The black and white curves are lines of constant stresses with label values in MPa. For illustrative purposes a brittle-plastic yield stress of 500 MPa is assumed.

Figure 2. Panel (a) shows the time-line sketch of our simulations. Panels (b) and (c) show the model configurations (b) for the forced subduction and (c) for the free subduction. Dark blue areas indicate the lithosphere. Brown areas indicate the initial weak zone. Light blue areas indicate the asthenosphere. Weak domain's width in panel (c) is 30 km.

Figure 3. Visualisations of the forced subduction model in panels (a-c), the free subduction model where the subduction continues (successful) with $t_{\text{free}} = 1.25$ Ma in panels (d-f), and the free subduction model where the subduction stops and delaminates (failed) with $t_{\text{free}} = 1.17$ Ma in panels (g-i). Material parameters are identical in all three simulations. The time evolution is chosen for different slab length. Panels (a), (d) and (g) show results for a slab of 75 km, the length of the slab required to initiate the free subduction. Panels (b), (e) and (h) show results for a slab of 310 km and subplots (c), (f) and (i) show results for a slab of 550 km. White lines show the isothermal contours for 200, 800 and 1440°C.

Figure 4. Diagrams showing the evolution of slab pull force with time, panel (a) is a zoom from panel (b). These diagrams evaluates the conditions required to develop a free subduction from the forced subduction simulation of reference S0 (in black). Free subduction simulations start after a period during which plates are pushed until initiation of free subduction. The different points in panel (a) show the slab pull force for different starting times (t_{free} , see Fig. 2a). This t_{free} is the duration of plate push to initiate the subduction in the initial part of the free subduction model simulation. Squares show conditions where free subduction failed, while circles show conditions where free subduction occurs. Black arrow indicates the minimum slab pull force needed to obtain a successful free subduction in S0 model. Inset figures, similar to panels (e) and (h) from Fig. 3, show examples of successful and failed free subduction models. White lines show the isothermal contours for 200, 800 and 1440 °C.

Forced subduction S0

Figure 5. Panels (a-c) show the evolution in time, same condition then Figs 3a-c, of the variations of total ΔGPE , ΔGPE beneath 80 km and topography for the forced subduction model. Vertical left (black) axes are for the ΔGPE values and vertical right (red) axes are for topography values. Panels (d-f) show the evolution of density in the region of the subduction zone at corresponding model times. White line is a temperature iso-contour for $1'440^\circ\text{C}$ representing the LAB. Black lines are iso-contours of density ($3'400$, $3'600$ and $3'800$ kg/m³).

Free subduction S1

Figure 6. Panels (a-c) show the evolution in time, same condition then Figs 3d-f, of the variations of total ΔGPE , ΔGPE beneath 80 km and topography for the free subduction model. Vertical left (black) axes are for the ΔGPE values and vertical right (red) axes are for topography values. Panels (d-f) show the evolution of density in the region of the subduction zone at corresponding model times. White line is a temperature iso-contour for 1440°C representing the LAB. Black lines are iso-contours of density (3400, 3600 and 3800 kg/m³).

Figure 7. Second strain rate invariant evolution for the forced subduction model, (a-c), and for the free subduction model, (d-f), same configuration as Figs 3a-f. White lines show the thermally controlled LAB defined as the 1440°C isotherm.

Figure 8. Zoom into the subduction zone of the forced subduction model for the time step corresponding to Fig. 7c. In panels (a-f) the results of individual strain rates for the different deformation mechanisms are displayed. Panel (a) shows total strain rate, (b) elastic strain rate, (c) plastic strain rate, (d) diffusion strain rate, (e) dislocation strain rate and (f) Peierls strain rate. Panel (g) shows distribution of deformation mechanism (elastic domain in yellow, plastic domain in light blue, dislocation creep in red, Peierls creep in dark blue and diffusion creep in orange) and panel (h) shows effective viscosity (Equation 15). White or black lines correspond to the thermally controlled LAB (1440°C isotherm).

Figure 9. Distribution of deformation mechanism evolution for the forced subduction model, (a-c), and for the free subduction model, (d-f), same time as Figs 3a-f. White lines correspond to the thermally controlled LAB (1'440°C isotherm).

Figure 10. Effective viscosity evolution for the forced subduction model, (a-c), and for the free subduction model, (d-f), same time as Figs 3a-f. Black lines correspond to the thermally controlled LAB (1'440°C isotherm).

Figure 11. Comparison of horizontal deviatoric stress between the forced subduction model (panels a-c) and the free subduction model (panels d-f) depicted at similar time as Figs 3a-f. Black lines correspond to the thermally controlled LAB (1'440°C isotherm). Areas in red, positive values, show regions associated with extension while areas in blue, negative values, show compression. Panels (g) and (h) show the principal stresses σ_1 in blue and σ_3 in cyan associated, respectively, to panels (c) and (f). The background shows phases and white lines show the isothermal contours for 200, 800 and 1'440°C.

Figure 12. Comparison between three forced subduction models with different elasticity parameters. Results of simulation S0 correspond to the black topography profile in panel (a), the horizontal deviatoric stress in panel (b) and the distribution of deformation mechanisms in panel (e). Results of simulation S3, with an unrealistically high shear modulus of $G = 3 \cdot 10^{12}$ Pa, correspond to the pink topography profile in panel (a), the horizontal deviatoric stress in panel (c) and the distribution of deformation mechanisms in panel (f). Results of simulation S4, with an unrealistically high shear modulus of $G = 3 \cdot 10^{13}$ Pa, correspond to the red topography profile in panel (a), the horizontal deviatoric stress in panel (d) and the distribution of deformation mechanisms in panel (g). Time step for panels (b) and (e) are the same as in Fig. 3c. Time step for panels (c and f) and (d and g) are chosen to have approximately the same depth of the slab as in panels (b and e) for reference. The dashed line in panel (a) shows the best fit of elastic flexure from the analytical formula from Turcotte & Schubert (2014) (Fig. 3.35 and equation 3.159, $x_b = 55$ km and $w_b = 0.5$ km). In panel (a) the horizontal position of the zero was displaced to match the position of the trench (but not for the other panels). In panels (b-d) areas in red, positive values, show regions associated with extension while areas in blue, negative values, show compression. In panels (b-g) white or black lines correspond to the thermally controlled LAB (1440°C isotherm).

Figure 13. Comparison between three forced subduction models where we change the friction angle of the lithosphere. Results of simulation S0 correspond to the black topography profile in panel (a), the horizontal deviatoric stress in panel (b) and the distribution of deformation mechanisms in panel (e). Results of simulation S5 correspond to the pink topography profile in panel (a), the horizontal deviatoric stress in panel (c) and the distribution of deformation mechanisms in panel (f). Results of simulation S6 correspond to the red topography profile in panel (a), the horizontal deviatoric stress in panel (d) and the distribution of deformation mechanisms in panel (g). Time step for panels (b) and (e) are the same as in Fig. 3c. Time step for panels (c and f) and (d and g) are chosen to have the same depth of the slab than in panels (b and e) as reference. Same references as in Fig. 12 for the dashed line in panel (a). The horizontal position of the zero in panel (a) is displaced to correspond to the position of the trench (but not for the other panels). In panels (b-d) areas in red, positive values, show regions associated with extension while areas in blue, negative values, show compression. In panels (b-g) white or black lines correspond to the thermally controlled LAB ($1'440^{\circ}\text{C}$ isotherm).

Figure 14. Colour plot of horizontal deviatoric stress for forced and free subduction with different boundary conditions.

Panels (a) and (b) show results of forced simulation S0 corresponding to the model where horizontal boundary velocities are

1042 applied on both sides of the model. Panels (c) and (d) show results of the same forced simulation, except that a horizontal
1043 boundary velocity is only applied on the right side of the model (simulation S7, Table 2). This velocity is twice as large as the
1044 one of model S0 to maintain the same absolute convergence velocity. Panels (e) and (f) show results of free simulation S1
1045 corresponding to the model where the lateral detachment of the slab by a weak zone is implemented at the right side of the
1046 model. Panels (g) and (h) show results of a free simulation where this detachment is applied at both sides of the model (S8).
1047 Time step for panels (a), (b), (e) and (f) same as Figs 3b, c, e and f. Time step for panels (c), (d), (g) and (h) are chosen to
1048 have the same corresponding depth of the slab (310 km and 425 km) for comparison. The areas in red, positive values, show
1049 regions associated with extension while areas in blue, negative values, show compression. Black lines correspond to the
1050 thermally controlled LAB (1'440°C isotherm).

1051

Figure 15. Comparison of the topography of the Mariana trench with modelled topography for the forced (S0) and free (S1) subduction models. The dashed line shows the best fit of elastic flexure from Turcotte & Schubert (2014) (Fig. 3.35 and equation 3.159, $x_b = 55$ km and $w_b = 0.5$ km). For comparison all topography profiles are co-located at the trench.

Figure 16. Free-air gravity anomaly comparison. Panel (a) shows the location of 10 different profiles across the Mariana Trench, with the WGM2012 free-air anomaly map in the background. Panel (b) shows in grey the observed profiles across the Mariana Trench, in red the synthetic profile from the forced subduction model for the time step corresponding to Fig. 3c, and in blue the synthetic profile from the free subduction model for the time step corresponding to Fig. 3f. A zoom on the trench was chosen for the horizontal position and all profiles were centred on the trench.

1068 *Table 1. Parameters used in the numerical simulations for the plastic and viscous rheology, namely dislocation creep, diffusion*
1069 *creep and Peierls creep. Parameters used for dry dislocation and dry diffusion mechanisms are from Hirth & Kohlstedt (2003).*
1070 *Parameters used for Peierls creep are from Kameyama et al. (1999).*

Adopted values of rheological and physical parameters					
Viscous rheology		Lithosphere, Asthenosphere and Weak zone and weak hydrated crust			
		Dislocation	Diffusion	Peierls	Units
F	invariant formulation correction factor	$1/6 \cdot 2^{(1/n)-3(n-1/2n)}$	$1/6 \cdot 2^{(1/n)-3(n-1/2n)}$	$1/6 \cdot 2^{(1/5)-3(5-1/25)}$	-
A	pre-exponential constant	$1.1 \cdot 10^{-16}$	$1.5 \cdot 10^{-15}$	$5.7 \cdot 10^{11}$	$[s^{-1} \cdot Pa^{-n} \cdot m^m]$
n	stress exponent	3.5	1	2	-
m	grain size exponent	0	3	-	-
E	activation energy	$530 \cdot 10^3$	$375 \cdot 10^3$	$5.4 \cdot 10^5$	$[J \cdot mol^{-1}]$
V	activation volume	$11 \cdot 10^{-6}$	$4 \cdot 10^{-6}$	0	$[m^3 \cdot mol^{-1}]$
γ	adjustable constant	-	-	0.1	-
σ_{pei}	the Peierls stress	-	-	8.5×10^9	$[Pa]$
Plastic rheology		Lithosphere	Asthenosphere	Weak zone / Sediments	
C	cohesion	$1 \cdot 10^7$	$1 \cdot 10^6$	$1 \cdot 10^6$	$[Pa]$
θ	Angle of internal friction	30	5	0	$[^\circ]$
Constants					
R	universal gas constant	8.31			$[J \cdot mol^{-1} \cdot K^{-1}]$
α	thermal expansion	$8 \cdot 10^{-6}$			$[K^{-1}]$
β	compressibility	$1 \cdot 10^{-11}$			$[Pa^{-1}]$
d	grain size	$5 \cdot 10^{-3}$			$[m]$
H_R	radiogenic heat production	$1 \cdot 10^{-10}$			$[W \cdot m^{-3}]$
G	shear modulus	$3 \cdot 10^{10}$			$[Pa]$
g	gravity	9.81			$[m \cdot s^{-2}]$
