Abstract

In volcanic environments, the presence of smectite may indicate re-
cent hydrothermal circulations. Smectite is also responsible for enhanced
rock electrical conductivity, as well as mechanical weakening. Therefore,

quantifying smectite is important in geothermal exploration. Smectite identification requires X-ray diffraction (XRD) but quantification based on XRD is time-consuming and not always accurate. In the present study, we investigate the use of an optimized unbuffered Cation Exchange Capacity (CEC) measurement, by back-titration of the Copper-triethylenetetramine(II) "Cu-trien" molecule, to quantify the smectite content of altered volcanic rock samples. We establish that a satisfying trade-off between the instrument uncertainty and an independant systematic error is theoretically reached for a fraction of reactants consumed of about 30% at the end of the exchange reaction. We suggest a modification to classical protocols to fall in that range. Finally, we show that optimized CEC measurements by Cu-trien are a direct measure of the smectite weight fraction in altered volcanic samples, with an average CEC of pure smectite of 90 ± 5 meq/100g.

1 Introduction

One of the challenges of geothermal exploration at volcanoes is to detect the presence of active hydrothermal circulations in fractures. Geo-electrical and electromagnetic measurements are commonly used to this aim because electrical resistivity contrasts can delineate zones of intense hydrothermal activity (e.g. Árnason et al., 2000; Flóvenz et al., 2005; Flóvenz et al., 2012). Electrical resistivity of volcanic rocks is particularly sensitive to the presence of secondary "alteration" minerals, often witnesses of hydrothermal circulations in fractures, such as clay minerals. The distribution of clay minerals can provide estimates of the temperature distribution in volcanic or sedimentary systems where their formation is controlled by the geothermal gradient (Alt et al., 1986; Bourdelle et al., 2013; Kristmannsdóttir and Tómasson, 1978; Kristmannsdottir, 1979). In active hydrothermal systems, the formation of smectite is not only controlled

32 by the geothermal gradient, but also by the convective activity related to recent
33 fault opening and causing boiling as well as chemical disequilibrium (Beaufort et
34 al., 1995; Bril et al., 1996; Patrier et al., 1996). Compared to other clay minerals
35 (e.g. illite, chlorite, kaolinite), smectite is much more conductive (e.g. Kaufhold
36 et al., 2014; Kaufhold et al., 2015) and contributes significantly to the electrical
37 conductivity of rocks, through Electrical Double Layer mechanisms (Flóvenz et
38 al., 1985; Pezard, 1990; Revil and Glover, 1997; Waxman and Smits, 1968) and
39 interfoliar conduction (Henry, 1997; Lévy et al., 2018; Maraqah et al., 1990).
40 Smectite is also abundant in subduction zones (Hyndman et al., 1997) and in
41 some major faults (Chester et al., 2013) and may play a role in the mechanical
42 weakening of altered volcanic rocks (Heap et al., 2014; Kaufhold et al., 2012;
43 Meller, 2014).

44 In order to study in the laboratory the influence of smectite on electrical
45 conductivity and mechanical properties of volcanic rocks, the smectite content
46 needs to be quantified first. Smectite content in drill-cuttings can also provide
47 estimates of the porosity or permeability in a reservoir, by comparison with
48 in-situ borehole resistivity logs (Flóvenz et al., 2005; Pezard, 1990; Revil et al.,
49 1998; Rink and Schopper, 1974; Waxman and Smits, 1968).

50 The primary goal of our study is to provide geothermal industry with a
51 simple method to quantify smectite content in hydrothermally altered volcanic
52 rocks. Quantifying smectite in altered volcanic rocks is challenging because a
53 large number of minerals often coexist in the same rock formation. Quantifi-
54 cation of smectite by Rietveld-refinements of X-ray diffraction (XRD) patterns
55 (e.g. Taut et al., 1998) is hampered when smectite-containing mixed layers co-
56 exist with smectite. Moreover, high-quality XRD scans are required for these
57 quantifications, which can be time-consuming.

58 Due to its particular crystalline structure, smectite has a much larger Cation

59 Exchange Capacity (CEC) than other clay minerals (Bouchet et al., 2000). This
60 CEC is mainly located in smectite interlayers (Dohrmann, 2006a; Lagaly, 1981;
61 Vogt and Köster, 1978). Hower and Mowatt (1966) found a linear correlation
62 between the CEC and the smectite fraction in a series of illite-smectite samples.
63 Kaufhold and Dohrmann (2003) also observed that the CEC measured by back-
64 titration of the Copper-triethylenetetramine(II) "Cu-trien" (Ammann et al.,
65 2005; Bergaya, 1997; Meier and Kahr, 1999) was proportional to the smectite
66 content in bentonites, qualitatively measured using the methylene blue method.

67 Altered volcanic rocks contain a larger variety of minerals than bentonite
68 or illite-smectite series, with often a large fraction of zeolites. Some zeolites,
69 such as clinoptilolite and heulandite, have a higher CEC than smectite, up
70 to 300 meq/100g, thanks to their wide solid solution of extraframework cations
71 (Fridriksson et al., 2004). However, the CEC of clinoptilolite drops to 5 meq/100g
72 when measured by the Cu-trien method (Meier and Kahr, 1999), because the
73 channels where extraframework cations are located cannot expand, unlike smec-
74 tite interlayers, so that only small cations (smaller than Cu-trien) can enter
75 clinoptilolite channels. Therefore, the Cu-trien molecule appears to be adequate
76 to quantify the smectite content in altered volcanic rocks. Our study tests this
77 possibility by comparing CEC measurements to smectite quantifications based
78 on Rietveld-refinements of XRD patterns, for samples where smectite is the only
79 swelling clay mineral.

80 Since altered volcanic rocks contain lower and more variable smectite content
81 than bentonite or illite-smectite series, the solid/solution ratio needs to be op-
82 timized for each sample, in order to minimize both the instrument uncertainty
83 and systematic biases. The need for optimization of the reactants (exchange
84 solution and sample) proportion was first addressed by Orsini and Remy (1976)
85 for CEC measurements with the Cobalti-hexamine molecule, "Co-hex", on large

86 masses of soil samples. Orsini and Remy (1976) pointed out that the exchange
 87 between Co-hex and soil samples could be considered as total only when the
 88 initial quantity of Co-hex was at least three times superior to the CEC. Yet,
 89 beyond eight times, the accuracy of the measurements would significantly de-
 90 crease. Based on these observations, the authors recommended to carry out
 91 experiments where the initial ratio between Co-hex and rock sample (expressed
 92 in CEC units) represents 30% to 80% of the CEC, or equivalently where the
 93 fraction of Co-hex consumed during the experiments ranges between 15% and
 94 30%. Further development of the Co-hex back-titration method (Cieselski et al.,
 95 1997; Ciesielski et al., 1997) allows extending the interval of Co-hex consumed
 96 to 5%-35%. The need to optimize the solid/solution ratio by adjusting the ini-
 97 tial mass of sample, for samples having a wide range of CEC values, is also
 98 discussed for the Cu-trien method by Dohrmann and Kaufhold (2009) and by
 99 Dohrmann (2006b) for the similar Ag-thiourea method.

100 Our study investigates the theoretical grounds for the observations of Dohrmann
 101 and Kaufhold (2009) and the ranges suggested by Orsini and Remy (1976) and
 102 Ciesielski et al. (1997) and presents a simple method for quantifying the smectite
 103 content of altered volcanic rocks through optimized CEC measurements using
 104 the Cu-trien exchange complex.

105 **2 Materials and Methods**

106 **2.1 Rock samples**

107 Thirty-eight samples from the Krafla high-temperature geothermal area are used
 108 in this study. Core samples are collected from four cored boreholes (KH1, KH3,
 109 KH5 and KH6) at varying depths. They represent a variety of lithologies and
 110 secondary minerals (Table 1). Cylindrical plugs (2-3 cm long and 2.5 cm diame-

ter) are prepared from the original core samples for petrophysical measurements, presented by Lévy et al. (2018). From the lateral faces of the plugs, thin sections and powders are prepared. Ten samples are used for optimization of CEC measurements, 24 samples for comparison between quantitative XRD analysis and CEC, 15 samples for chemical analysis by Electron Probe Micro Analysis (EPMA) and four samples for ICP analyses of exchangeable cations. Some samples are used for more than one type of analysis (Table 1).

Table 1: Description of the 38 samples used in this study (ID = sample name). The borehole (BH) and depth (in meters) from which the samples are extracted are indicated in Columns 2 and 3. The type of analysis for which the samples are used are indicated in Columns 4 to 6, where Opt_{CEC} corresponds to the optimization of CEC measurements. The CEC (in meq/100g) and the smectite weight per cent measured by XRD are given in Columns 7 and 8. The lithology (Litho) is given in Column 9; hyalo = hyaloclastite; v. lava = vesicular lava; d. lava = dense lava; ignimb. = ignimbrite. The presence of secondary minerals (if more than 1% as quantified by XRD quantification) is indicated in Columns 10 to 17. Sm = smectite; Chl = chlorite; Heu = heulandite (zeolite); Qtz = quartz; Clc = calcite; Pyr = pyrite; Tit = titanite; Oth. = other; Laum = laumontite (zeolite); Act = actinolite; Ep = epidote; Wai = wairakite; Ana = anatase; Jad = jadeite; Sid = siderite.

118 A first set of powders is used for the analysis of CEC uncertainty, carried out
119 on 88 samples but presented here for 10 relevant samples. This set of powders
120 is roughly grained to powder size, without any size control.

121 A second set of powders is used for XRD scans and associated mineral quan-
122 tification by Rietveld-refinements. Powders from the first set are further ground
123 for 10 minutes in ethanol, using an automatic grinder Retsch RM 200, dried and
124 sieved before being prepared as randomly oriented mounts. For each sample,
125 the exact same powder is used later on for independent CEC measurements that
126 are later compared to XRD mineral quantification.

127 2.2 Mineral quantification by X-ray Diffraction

128 The powders are front-loaded onto the sample holder, using a razor blade to
129 smooth out the surface, in order to minimize preferred orientation (PO) and
130 shift of diffraction peaks (Bish and Reynolds, 1989). An example of PO issues
131 when the sample is back-loaded is shown in Appendix A. The XRD scans are
132 carried out over the range $4-75^\circ 2\theta$ ($4-65^\circ 2\theta$ for a few samples) with a Philips
133 X’Pert Pro (radiation Cu-K α ; 45 kV; 30 mA; step size 0.0167° ; time per step 240
134 s; X’Celerator Scientific high-speed detector; 240 mm goniometer radius). The
135 XRD patterns are analyzed quantitatively with the Rietveld program BGMN
136 and the Profex user-interface (Doebelin and Kleeberg, 2015; Taut et al., 1998).
137 The following mineral phases are considered for the refinements: forsterite,
138 labradorite, bytownite, orthoclase, albite, augite, diopside, kanoite, smectite-
139 tri, zeolite (heulandite, clinoptilolite, philippsite, dachiardite, laumontite, anal-
140 cime), pyrite, ilmenite, titanomagnetite, jadeite, siderite, hematite, maghemite,
141 anatase, titanite, schorl, chlorite, calcite, quartz, wairakite, prehnite, epidote,
142 actinolite, garnet, grossular. Two examples of refinements are shown, in Figure
143 1 for a sample containing smectite as the only clay mineral and in Figure 2 for

144 a sample containing smectite, chlorite, and most likely chlorite-smectite.

Figure 1: XRD quantitative analysis, using the BGMN software, for sample L15 containing smectite as the only clay mineral. The resulting mineral percentages and fit quality are indicated on the graph.

145 In samples containing a mixture of disordered clay phases (such as smectite
 146 and smectite-containing mixed layers and/or disordered 1:1 minerals), smectite
 147 content is difficult to quantify accurately by Rietveld-refinements, because of
 148 the strong correlation between parameters, including background (e.g. Raven
 149 and Self, 2017). XRD patterns of samples containing both smectite and chlorite
 150 can be fitted (Figure 2) but the software adjusts both the chemical compo-
 151 sition of chlorite and the relative quantity of chlorite and smectite to fit the
 152 relative intensities of the d(001) peak at 14-15Å and the d(002) peak at 7.2Å.
 153 This results in the non-uniqueness of the model parameters related to chlorite
 154 chemistry and smectite and chlorite quantities. The chemistry of chlorite can be

155 constrained (especially the relative abundance of Fe and Mg), based on indepen-
 156 dent chemical analyses, but this requires a large number of EPMA on polished
 157 thin sections, to obtain a representative chemical composition of chlorite for
 158 the sample, which is time-consuming and expensive. Moreover, assuming that
 159 the chemistry of chlorite can be properly constrained, the combined presence
 160 of smectite and chlorite often implies the presence of a chlorite-smectite phase.
 161 This chlorite-smectite phase also contributes to the d(001) peak at 14-15Å and
 162 its contribution can hardly be discriminated from that of pure smectite. As a
 163 result, the fitted amount of "smectite" corresponds in reality to a quantity of
 164 smectite + chlorite-smectite. Since only the quantity of smectite layers matters
 165 for the comparison to the CEC, not the quantity "smectite+ chlorite-smectite",
 166 this quantification is not appropriate. Therefore, only smectite quantifications
 167 for samples containing no other clay phase are used in this study for further
 168 comparison to CEC measurements.

169 Special studies are necessary to determine the exact type of smectite present
 170 in each sample, especially regarding the type of interlayer cation (Ca^{2+} or Na^{+}),
 171 the number of water layers surrounding interlayer cations and the tri- or dioc-
 172 tahedral character. The tri- or dioctahedral character mainly influences the
 173 d(060) diffraction peaks, at high angles, which have a lower intensity and are
 174 overlapping with other minerals such as quartz. These high-angle peaks only
 175 negligibly affect (if at all) the refinement. On the other hand, low-angle peaks,
 176 especially the d(001) around 14-15Å, which is influenced by the composition of
 177 the interlayer space both in terms of cation and water layer, significantly affect
 178 the refinement. Therefore, the patterns are fitted with two different types of
 179 smectite phases: a phase corresponding to a "tri-octahedral smectite with in-
 180 terfoliar spaces filled with Ca, accompanied by two water layers", and another
 181 tri-octahedral smectite "saponite" with more flexible interlayer distance (see de-

Figure 2: XRD quantitative analysis, using the BGMN software, for a sample containing smectite, chlorite and mixed layer chlorite-smectite.

tailed structure files in Appendix B). An uncertainty on the smectite content is calculated based on the discrepancy between the two fits. For the other minerals, the uncertainty is calculated based on the variance of the model parameters given by the software.

2.3 CEC determination

The CEC of altered volcanic rocks is measured by back-titration of the Copper-triethylenetetramine (Cu-trien) molecule, as in the original protocol designed by Meier and Kahr (1999) to measure the CEC of pure clay samples. This molecule is also used, for example, by Kaufhold and Dohrmann (2003) to measure the CEC of bentonites.

First, the sample is weighted in a beaker and then 50 ml of deionized water, measured with a volumetric flask, are added into the beaker. The few remaining

194 water drops in the volumetric flask, after adding water to the beaker, represent
 195 an average of 0.6 ± 0.2 . In order to reduce the uncertainty on the water volume,
 196 we measure the exact mass of water added to the beaker and adjust it by
 197 weight as close as possible to 50.00 g. Without this weight adjustment and
 198 measurement, the volume of water added is 49.4 ± 0.2 ml. The beaker containing
 199 the water-rock mixture is then left in an ultrasonic bath for 5 minutes. Next,
 200 10 ml of Cu-trien at about 1.10^{-2} mol/L are added with a 5 ml pipette (two
 201 steps). Details about the preparation and characterization of the exchange
 202 Cu-trien solution at 1.10^{-2} mol/L are given in Appendix C. The exchange is
 203 considered complete after 5 minutes of magnetic stirring. Since most of the
 204 exchange is expected to occur within interlayer spaces of swelling clay minerals
 205 (smectite), 5 minutes are considered sufficient. A test, carried out on sample
 206 L126, indicates that the difference in exchange yield after 5 and 60 minutes is
 207 within the instrument uncertainty, and thus not significant (see more details in
 208 Appendix C). If the CEC of higher charge clay minerals (e.g. vermiculite) were
 209 investigated, longer contact times might be needed (Von Reichenbach, 1968).

210 After the exchange reaction is completed, solid and liquid are separated by
 211 centrifugation. Finally, the absorbance of the supernatant solution is measured
 212 by a spectrophotometer at 578 nm. The absorbance of the Cu-trien solution
 213 before exchange, prepared independently by mixing 50 ml of deionized water and
 214 10 ml of Cu-trien at 1.10^{-2} mol/L, is also measured. The CEC (in meq/100g)
 215 is then calculated with Equation 1.

$$CEC_{lab} = \frac{2(C_i - C_f)V}{m} \quad (1)$$

216 where V is the total volume of the solution (60 ml), m is the rock mass in
 217 mg and C_i and C_f are the Cu-trien concentrations in the initial and final solu-
 218 tions, respectively, in mol/L. C_i and C_f are calculated based on the absorbance

219 measurements and the calibration curve presented in Appendix C.

220 The rock mass suggested by Meier and Kahr (1999) is 200 mg but is a key
221 parameter to be adjusted: m varies between 100 and 1000 mg in our experi-
222 ments (see e.g. Dohrmann, 2006b; Dohrmann and Kaufhold, 2009). If the CEC
223 can be approximately estimated, e.g. thanks to XRD measurements and rapid
224 evaluation of the d(001) peak of smectite at 14-15Å, the mass of rock is chosen
225 accordingly. If the d(001) is intense compared to other peaks and no d(002) at
226 7.2Å is observed, meaning that there is little to no chlorite or chlorite-smectite,
227 then 200 mg of rock sample are considered appropriate. If chlorite or chlorite-
228 smectite are present in significant amount (e.g. if d(002) more intense than
229 d(001)), 400 mg are used. If the d(001) peak is absent or small compared to the
230 background, then 1000 mg are used. If no assumption on the smectite amount
231 can be made priori to CEC measurement, then a first measurement with 200 mg
232 is carried out. After the first CEC measurement, the mass of rock is adjusted
233 accordingly to the result for the next measurement. At least two measurements
234 with the same rock mass are carried out for each sample.

235 The protocol and equation presented here-above uses rock masses as dried at
236 room temperature. The water content is determined independently by weighting
237 a given mass of sample at room temperature and after drying in an oven at
238 105°C. Water content measurements, as well as corresponding correction of
239 CEC values, are presented in Appendix D.

240 **2.4 Analysis of exchangeable cations in smectite**

241 Chemical analyses of clay minerals are carried out on 15 polished thin sections
242 at Géosciences Montpellier, using a CAMECA SX100 electron microprobe (22
243 keV, 10 nA). The 15 samples used for these measurements are indicated in Table
244 1.

Inductively Coupled Plasma Atomic Emission Spectroscopy (ICP-AES) analyses are carried out at ÍSOR to characterize the main cations exchanged after reaction with Cu-trien. Magnesium, calcium and sodium concentrations are measured at the wavelengths 279.079, 373.690 and 589.592 nm, respectively. The exchangeable cations of four samples are investigated by this method: L119, L96, 31 and L99. Solutions are analysed at three steps of the reaction for each sample: after mixing rock and water, after ultra-sonic bath and after exchange with Cu-trien. This allows not taking into account cations coming from basic water-rock interaction (e.g. dissolution of glass or minerals).

3 Results and Discussion

3.1 Estimation of the laboratory uncertainty

We calculate the total uncertainty on the CEC measurements, u_{tot} , by taking into account measurement dispersion, u_{disp} , and instrument resolution, u_{instr} . The general formula, based on the rule of error propagation by Taylor expansions, is presented in Equation 2 (e.g. Joint Committee for Guides in Metrology (JCGM), 2008; Ku, 1966).

$$\begin{aligned}
 u_{tot}(CEC) &= \sqrt{u_{instr}(CEC)^2 + u_{disp}(CEC)^2} \\
 u_{disp}(CEC) &= \sqrt{\frac{1}{n(n-1)} \sum_{i=1}^n (CEC_i - CEC_{avg})^2} \\
 \frac{u_{instr}(CEC)}{CEC} &= \sqrt{\left(\frac{u(V)}{V}\right)^2 + \left(\frac{u(m)}{m}\right)^2 + \left(\frac{u(C_i - C_f)}{C_i - C_f}\right)^2} \quad (2)
 \end{aligned}$$

where n is the number of measurements for each sample, usually two or three, and CEC_{avg} the average of the n measurements. $u(V)$ and $u(m)$ are the uncer-

263 tainties on volume and mass, respectively, and $u(C_i - C_f)$ the uncertainty on
 264 the difference between initial and final concentrations. We explain below how
 265 these three terms are calculated.

266 The uncertainty on rock weighting is estimated to $u(m) = 0.5$ mg, based on
 267 the variations of the last digit of the scale.

The uncertainty on the total volume (60 ml) measurement is calculated by propagating the uncertainty of the three measured volumes (see Equation 3).

$$V = V_{wat} + 2V_{pip}$$

$$u(V) = \sqrt{u(V_{wat})^2 + 2u(V_{pip})^2} \quad (3)$$

268 where $u(V_{wat})$ is the uncertainty on the 50 mL of water and $u(V_{pip})$ is the
 269 uncertainty on the 5 ml of Cu-trien (measured twice with a 5 ml micropipette
 270 to obtain 10 ml). $u(V_{pip})$ is estimated to 0.02 mL (by pipetting step). $u(V_{wat})$
 271 is reduced from 0.20 to 0.01 ml when the exact mass of water added to the rock
 272 is measured. This results in a total volume uncertainty $u(V) = 0.03$ ml, while it
 273 amounts to $u(V) = 0.20$ ml when the water is directly added from the volumetric
 274 flask without further verification.

The calculation of the uncertainty on the concentration difference is presented in Equation 4.

$$A_i - A_f = L(C_i - C_f)$$

$$\left(\frac{u(C_i - C_f)}{C_i - C_f}\right)^2 = \left(\frac{u(A_i - A_f)}{A_i - A_f}\right)^2 + \left(\frac{u(L)}{L}\right)^2$$

$$= \frac{u(A_i)^2 + u(A_f)^2}{(A_i - A_f)^2} + \left(\frac{u(L)}{L}\right)^2 \quad (4)$$

275 where A_i and A_f are the initial and final absorbance, respectively, and $u(A_i) =$
 276 $u(A_f)$ their respective uncertainty. L is the slope of the calibration curve (ab-

sorbance versus concentration, see Appendix C) and $u(L)$ is calculated using the error propagation rule presented above, with an expression of L based on the two extreme calibration points and their respective uncertainty (Joint Committee for Guides in Metrology (JCGM), 2008).

The uncertainty on the absorbance measured by the spectrophotometer is considered to be 0.001, based on the dispersion observed for repeated measurements of the same solution, as well as the spectrophotometer resolution provided by the manufacturer.

The total instrument relative uncertainty is given by Equation 5.

$$\frac{u_{instr}(CEC)}{CEC} = \sqrt{\frac{u(V_{flask})^2 + 2u(V_{pip})^2}{V^2} + \frac{u(m)^2}{m^2} + \frac{2u(A_i)^2}{(A_i - A_f)^2} + \frac{u(L)^2}{L^2}} \quad (5)$$

3.2 Increasing the rock mass decreases the laboratory uncertainty for low-CEC rocks

Based on Equation 5, we calculate, for six samples, the instrument uncertainty of CEC measurements using two different initial rock masses and the same initial Cu-trien solution. We show that the relative uncertainty decreases from up to 70% to less than 5% when increasing the rock mass from the 200 mg, as recommended for example by Meier and Kahr (1999), to 1000 mg (Figure 3). In the present case, increasing the rock mass from 200 to 1000 mg increases the fraction of Cu-trien consumed from less than 1% to about 13% (Sample L114 in Figure 3).

Figure 3 shows that the instrument uncertainty exponentially decreases with the fraction of Cu-trien consumed. This is consistent with Equation 5, where the denominator $(A_i - A_f)^2$ controls the overall value of $u(CEC)$ because $\frac{u(V)}{V}$

Figure 3: Measured CEC and relative laboratory (instrument) uncertainty as a function of the fraction of Cu-trien consumed. The circles with error bars correspond to the measured CEC (left axis) and the stars to the uncertainty, as calculated in Equation 5 (right axis). An increased fraction corresponds to an increased mass of rock initially present. Each color corresponds to one sample. The six samples used in this figure have a CEC lower than 5 meq/100g. Error bars (both positive and negative) are calculated as the product of the measured CEC by the relative uncertainty.

300 and $\frac{u(m)}{m}$ are very small compared to the third term. This is particularly true
 301 for samples with CEC lower than 5 meq/100g, i.e. with low smectite content.
 302 This effect is due to the limited number of digits, which can be read on the
 303 spectrophotometer (only three digits, with values always ≤ 1).

304 3.3 Increasing the rock mass decreases the yield of the 305 exchange reaction for high-CEC rocks

306 For high-CEC samples, we observe that the measured CEC can decrease by up
 307 to 50% when the rock mass is increased, for fixed initial volume and concen-
 308 tration of Cu-trien (Figure 4). Dohrmann and Kaufhold (2009) suggest that
 309 an unsuitably small solution/solid ratio may result in a reduced selectivity of
 310 the index cation (Cu-trien in their case) and thus in an incomplete exchange of

interlayer cations. A similar observation is mentioned in Cieselski et al. (1997) for CEC measured by the Co-hex index cation and attributed to a reduced yield of the exchange reaction when the fraction of Co-hex consumed exceeds a threshold.

Here, we investigate the mathematical expression of these empirical observations, in order to predict the yield of the exchange reaction between Cu-trien and the rock sample and determine an acceptable threshold of Cu-trien consumption at the end of the reaction. The yield of the exchange reaction is taken as the relative difference between the apparent measured CEC, $CEC_{app} = CEC_{lab}$, and the maximum CEC, CEC_0 . We first write the theoretical relationship between CEC_{app} and CEC_0 .

Figure 4: Measured CEC with different initial ratios of reactants (Cu-trien and rocks) for four samples (blue filled circles): L99, L9, L6 and L119. The initial concentration of Cu-trien is about constant ($(1.6 \pm 0.1) \cdot 10^{-3}$ mol/L) but the mass of rock varies between 100 and 1000 mg (top x-axes). The fraction of Cu-trien consumed at the end of the reaction is marked aside each measurement. The laboratory (instrument) uncertainty is smaller than the symbols. The model predictions for four values of the thermodynamic constant K are also displayed as plain lines with a warm colorscale. The values of K are chosen on a trial-error basis, assuming $K \geq 1$. The value of CEC_0 used for these predictions is marked together with the name of the sample, and corresponds to the measured CEC for the highest initial ratios. The values of CEC_0 may differ from the values given in Table 1 because a different set of powder is used for these measurements than for the measurements related to the correlation with XRD refinements.

For simplification purposes, we consider only one bivalent exchange reaction,

323 between the Cu-trien(II) cations and Ca^{2+} cations filling the exchange sites
 324 in the rock samples. According to chemical analyses of the smectite grains
 325 carried out by EPMA, there is at least twice as much Ca^{2+} filling the interlayer
 326 spaces than Na^+ . There is an overall abundance of Mg^{2+} in the structural
 327 formula of these saponites but EPMA does not allow differentiating Mg^{2+} in
 328 the crystal lattice from Mg^{2+} in the interlayer space. The concentration of Mg,
 329 Ca and Na, measured by ICP in the solutions after exchange with Cu-trien for
 330 four samples, indicate that no Na has been exchanged and that exchanged-Ca
 331 and exchanged-Mg represent 72-94% and 8-13% of the total cation exchange
 332 capacity, respectively. These two types of result confirm that bivalent cations
 333 represent the majority of interlayer cations and the exchange ratio with Cu-
 334 trien(II) will be mostly 1:1 (Figure 5).

335 The chemical exchange reaction, considering a majority of Ca^{2+} in the initial
 336 state, is written in Equation 6.

337 The thermodynamic constant K of this exchange reaction is defined in Equa-
 338 tion 7.

$$K = \frac{X_{Cu,eq} a_{Ca,eq}}{X_{Ca,eq} a_{Cu,eq}} \quad (7)$$

339 where the subscript "eq" indicates that a chemical equilibrium is reached. $X_{Cu,eq}$
 340 and $X_{Ca,eq}$ are the dimensionless chemical activities of cations Cu-trien(II) and
 341 Ca^{2+} filling sites in the rock at the end of the exchange reaction, respectively,
 342 and $a_{Cu,eq}$ and $a_{Ca,eq}$ are the dimensionless chemical activities of cations Cu-
 343 trien(II) and Ca^{2+} in the aqueous solution at the end of the exchange reaction,
 344 respectively. Chemical activities are defined in Equation 8, where the subscript
 345 "eq" is removed for clarity purposes, but we assume the thermodynamic equi-

Figure 5: Number of exchangeable Ca-ions compared, to Na-ion and Mg-ion in the interlayer spaces of smectites. The relative number of exchangeable Ca versus Na is shown as a function of sampling depth. Sixteen samples, where chemical analyses by electron probe are carried out, are reported on this figure: L04 to L31 from KH1, L40-L58 from KH5 and L81-L99 from KH6. The error bar indicates the range of values found for the different smectite grains measured in each thin section. The histogram at the center shows the distribution of exchangeable Mg and Ca in four samples, as measured by ICP in the exchange solutions after reaction with Cu-trien. The sodium concentration in the solutions after exchange is not significantly higher than in the solutions before exchange (both before and after ultra-sonic bath) for any of the samples. Both types of measurements are available for two samples (L31 and L99).

346 librium is reached.

$$\begin{cases} a_{Cu} = [Cu]_{aq} \\ a_{Ca} = [Ca]_{aq} \\ X_{Cu} = \frac{meq(Cu)}{mCEC_0} \\ X_{Ca} = \frac{meq(Ca)}{mCEC_0} \end{cases} \quad (8)$$

347 where $[Cu]_{aq}$ and $[Ca]_{aq}$ are the chemical concentrations of cations (Cu-
348 trien(II) and Ca^{2+} , respectively) in the aqueous solution, in mol/L, and $meq(Cu)$

349 and $meq(Ca)$ are the quantities of cations (Cu-trien(II) and Ca^{2+} , respectively)
 350 filling sites in the rock, in millimol equivalent "meq". Each mmol of Cu-trien(II)
 351 or Ca^{2+} corresponds to 2 meq, given the double positive charge carried by each
 352 cation. a_{Cu} and a_{Ca} are normalized by an "infinite" theoretical concentration
 353 of 1 mol/L. With CEC_0 being the total CEC of the rock, in meq/g, and m the
 354 mass of rock considered in the experiment, in g, $mCEC_0$ is the total number
 355 of exchange sites available in the rock, in meq. According to these definition,
 356 $[Cu]_{aq}$, $[Ca]_{aq}$, $meq(Cu)$ and $meq(Ca)$ are given in Equation 9.

$$\begin{cases} [Cu]_{aq} = C_f \\ [Ca]_{aq} = C_i - C_f \\ meq(Cu) = mCEC_{app} \\ meq(Ca) = m(CEC_0 - CEC_{app}) \end{cases} \quad (9)$$

357 Combining Equations 7, 8 and 9, the thermodynamic constant, K , can be
 358 written as in Equation 10.

$$K = \frac{meq(Cu)}{meq(Ca)} \times \frac{C_i - C_f}{C_f} = \frac{CEC_{app}}{CEC_0 - CEC_{app}} \times \frac{C_i - C_f}{C_f} \quad (10)$$

Given that $CEC_{app} = CEC_{lab}$ and following Equations 1, 9 and 10, $meq(Cu)$
 and $meq(Ca)$ can also be written, as in Equation 11.

$$\begin{cases} meq(Cu) = 2V(C_i - C_f) \\ meq(Ca) = \frac{meq(Cu)(C_i - C_f)}{KC_f} = \frac{2V(C_i - C_f)^2}{KC_f} \end{cases} \quad (11)$$

Assuming that all exchange sites are filled with either Cu-trien(II) or Ca^{2+}

at the end of the reaction, the total CEC, CEC_0 , is described in Equation 12.

$$\begin{aligned}
CEC_0 m &= meq(Cu) + meq(Ca) \\
\iff CEC_0 &= \frac{2(C_i - C_f)V}{m} \left(1 + \frac{(C_i - C_f)}{KC_f}\right) \\
\iff KC_f CEC_0 &= CEC_{app}(KC_f + C_i - C_f) \\
&= CEC_{app}[(K - 1)C_f + C_i] \\
\iff C_f &= C_i \times \frac{CEC_{app}}{KCEC_0 + (1 - K)CEC_{app}} \quad (12)
\end{aligned}$$

By writing C_f as a function of C_i , m , V and CEC_{app} (Equation 1), Equation 12 gives Equation 13.

$$\begin{aligned}
C_i - \frac{mCEC_{app}}{2V} &= C_i \times \frac{CEC_{app}}{KCEC_0 + (1 - K)CEC_{app}} \\
\iff (KCEC_0 + (1 - K)CEC_{app}) \times (2VC_i - mCEC_{app}) & \\
&= 2VC_i CEC_{app} \quad (13)
\end{aligned}$$

Equation 13 can be re-written as a second-order equation of the variable $Y = CEC_{app}$ (Equation 14).

$$\begin{aligned}
(1 - K)Y^2 + (KCEC_0 + \frac{2VKC_i}{m})Y - \frac{2VKC_iCEC_0}{m} &= 0 \\
\iff aY^2 + bY + c = 0 &\begin{cases} a = 1 - K < 0 \\ b = KCEC_0 + \frac{2VKC_i}{m} \\ c = -\frac{2VKC_iCEC_0}{m} \\ \Delta = b^2 - 4ac \end{cases} \quad (14)
\end{aligned}$$

with $a < 0$ because $K > 1$ (otherwise no exchange would occur). By solving the second-order equation (14) and keeping only the positive solution (which remains positive even if $K < 1$), we obtain an explicit function for CEC_{app}

(Equation 15).

$$\begin{aligned}
Y = CEC_{app} &= \frac{-b + \sqrt{\Delta}}{2a} \\
&= \frac{-(\alpha + X) + \sqrt{(\alpha + X)^2 + 2\alpha\beta X}}{\beta} \left\{ \begin{array}{l} X = 2V \frac{C_i}{m} \\ \alpha = CEC_0 \\ \beta = 2 \frac{1-K}{K} < 0 \end{array} \right. \quad (15)
\end{aligned}$$

359 The function of X presented in Equation 15 increases monotoneously with X
 360 and reaches asymptotically the value of CEC_0 . Since X is inversely proportional
 361 to m , the sequence of equations presented here predicts that an increase of
 362 rock mass (all other things being equal) will increase the difference between
 363 CEC_{app} and its asymptote CEC_0 , which is equivalent to reducing the yield of
 364 the exchange reaction.

365 This model based on simple assumptions predicts the observations of Dohrmann
 366 and Kaufhold (2009) and Cieselski et al. (1997) that the sample mass is the de-
 367 termining factor for optimum precision of the CEC and exchangeable cations,
 368 if the same volume of solution is used. The function presented in Equation 15
 369 can also predict our experimental observations on samples with large smectite
 370 volume, provided that CEC_0 is chosen accordingly (Figure 4). Values of K in
 371 the range 10-100 are consistent with the observations but the value of K does
 372 not affect much the predictions. Given the limited sensitivity of the model to
 373 the value of K , we do not attempt here to evaluate precisely this constan. We
 374 only suggest that the range 20-50 is appropriate to describe the reaction taking
 375 place in the samples shown in Figure 4. In reality, K depends not only on the
 376 exchanged cation but also on the type of minerals and of sites involved in the
 377 exchange (Tertre, 2014; Reinoso-Maset et al., 2012; Durrant et al., 2018; Robin
 378 et al., 2015; Robin et al., 2017).

379 3.4 Optimization of the CEC measurements

Equations 16 and 17 describe the "partial exchange" systematic error and "instrument" uncertainty, as a function of the fraction $x = \frac{C_i - C_f}{C_i}$ of Cu-trien consumed after the reaction, based on Equations 12 and 5, respectively.

$$Err_{partial} = \frac{CEC_0 - CEC_{app}}{CEC_{app}} = \frac{(C_i - C_f)}{KC_f} = \frac{x}{K(1-x)} \quad (16)$$

$$\begin{aligned} \frac{u_{instr}(CEC)}{CEC} &= \sqrt{\frac{u(V_{flask})^2 + 2u(V_{pip})^2}{V^2} + \frac{u(m)^2}{m^2} + \frac{2u(A_i)^2}{(A_i - A_f)^2} + \frac{u(L)^2}{L^2}} \\ &= \sqrt{\frac{u(V_{flask})^2 + 2u(V_{pip})^2}{V^2} + \frac{u(m)^2}{m^2} + \frac{2u(A_i)^2}{x^2 A_i^2} + \frac{u(L)^2}{L^2}} \quad (17) \end{aligned}$$

380 Depending on the value of the thermodynamic constant, K , the optimal
 381 fraction of Cu-trien consumed to minimize both the instrument uncertainty
 382 and the partial exchange systematic error is somewhere between 30% and 80%
 383 (Figure 6), as suggested empirically for CEC measurements with Co-hex on soils
 384 by Orsini and Remy (1976). Since it is not possible to determine K with these
 385 simple measurements, we consider most resonable to aim at 30% consumption
 386 (most pessimistic value for K) because the decrease of $u_{instr}(CEC)$ beyond 30%
 387 is less important.

388 3.5 Quantification of smectite weight fraction in altered 389 volcanic rocks

390 A linear correlation is found between the smectite weight fraction and the CEC
 391 of altered volcanic rocks, where the only swelling clay mineral is smectite (Figure
 392 7). Due to the complexity of Rietveld refinements in whole rock samples when
 393 several types of clays are involved, only samples where a satisfying fit is obtained
 394 using only the clay phase "Smectite tri-octahedral with interlayers filled with Ca
 395 and 2 water layers" are reported in this figure. In samples where a peak at 7-

Figure 6: Laboratory uncertainty and "partial exchange" systematic error, as a function of the fraction of Cu-trien consumed.

396 7.5Å is observed (typical of chlorite and chlorite-smectite), the smectite quantity
 397 derived from the fit is considered irrelevant for a quantitative comparison with
 398 the CEC. An uncertainty on the quantification is calculated by fitting the same
 399 diffraction patterns with a different smectite phase: "Saponite with interlayers
 400 filled with undetermined cations and 2 water layers". The quantities derived
 401 from the fit with the less constrained saponite are systematically lower. The
 402 linear fit to the observations shown in Figure 7 has a slope $CEC_{smec} = 90 \pm$
 403 5 meq/100g and a regression coefficient $R^2 = 0.945$. The slope is consistent
 404 with the known range of CEC for smectite, 80-120 meq/100g, caused by the
 405 permanent negative charge of the crystal lattice, in the range 0.3-0.6 per half
 406 unit cell $Si_4O_{10}(OH)_2$, that is compensated for hydrated interlayer cations (e.g.
 407 Bouchet et al., 2000). A slope of $CEC_{smec, 105^\circ C} = 94 \pm 5 \text{ meq/100g}$, with a

408 regression coefficient of 0.952, is found when CEC values are corrected for the
 409 water loss at 105°C (Appendix D).

Figure 7: CEC measurements versus smectite quantification by Rietveld refinements of XRD patterns, for samples where smectite is the only swelling clay mineral. The slope and regression coefficient of the fitting line is given in the legend. CEC measurements and XRD scans are carried out on the exact same powders. The same figure, using CEC values corrected for taking the water content into account in each sample, is presented in Appendix D.

410 The contribution of other minerals to the measured CEC is also investigated,
 411 in particular zeolites, illite and chlorite. Zeolites can be divided into two groups:
 412 (i) "rigid" zeolites (e.g. laumontite, mesolite, analcime, natrolite and scolecite),
 413 whose chemical formula is well-defined and in which extra-framework (other
 414 than Al and Si) cations cannot be exchanged and only the water content can
 415 vary and (ii) "flexible" zeolites (e.g. heulandite, chabazite and clinoptilolite),
 416 which exhibit a wide and continuous range of extra-framework cation compo-
 417 sitions. Although, CEC of heulandite and clinoptilolite can reach up to 300
 418 meq/100 g (Fridriksson et al., 2004), CEC measurements by the method de-

419 veloped here result in CEC values in the range 0.5-1.5 meq/100g (Lévy et al.,
420 2018). Therefore, the contribution of zeolites to the CEC measured by Cu-trien
421 in altered volcanic samples is negligible.

422 The CEC of pure illite [Beavers Bend illite - Mankin and Dodd (1961)] is
423 also measured using the same method (back-titration by Cu-trien), yielding
424 4 meq/100g, which confirms the quasi-absence of non-mica layers in the illite
425 sample (Mankin and Dodd, 1961) and the negligible CEC of pure illite compared
426 to pure smectite (Hower and Mowatt, 1966). Moreover, the CEC of samples
427 containing large amounts of chlorite, as well as in some cases wairakite and
428 other "high-temperature" alteration minerals (epidote, actinolite), but no hint
429 of smectite, is always lower than 0.5 meq/100g, when measured by this method
430 (Lévy et al., 2018). We conclude that the linear trend presented in Figure 7 can
431 be used to estimate the weight fraction of smectite in altered volcanic samples
432 containing wide range of minerals. This weight fraction also includes smectite
433 layers in mixed-layer chlorite-smectite or illite-smectite.

434 As mentioned in Section 2, the grain size of rock powders used for measure-
435 ments presented in Figure 7 is strictly below 250 μm . This is a requirement to
436 transform the CEC measurement into absolute smectite weight fraction. The
437 presence of larger grains (e.g. millimetric size) have less surface exposed during
438 the exchange reaction, which might result in reduced smectite accessibility by
439 the exchange solution and thus smaller measured CEC (Kaufhold et al., 2012).
440 We do observe a discrepancy of 20% for a high-CEC sample, L99, between the
441 CEC measured with the same initial and optimal conditions but ground to two
442 different sizes. These two measurements were carried out by the Institut Na-
443 tional de Recherche en Agronomie in Arras (France), which performs accredited
444 measurements of CEC on soil: (i) using their standard size ($\leq 2 \text{ mm}$) and (ii)
445 using a smaller size ($\leq 250 \mu\text{m}$) on our request.

446 Finally, heterogeneity of core samples from geothermal areas may cause sig-
447 nificantly different CEC values depending on which lateral face of the cylindrical
448 plug is used for the powder. Therefore, crushing and mixing together as much
449 rock sample as possible (e.g. from the two lateral faces) is recommended.

450 4 Conclusions

451 In this study, we suggest a modified protocol to minimize the uncertainty of CEC
452 measurements with the Cu-trien method and thus to quantify the smectite con-
453 tent in altered volcanic rocks. We observe that using a fixed mass of sample for
454 rocks covering a wide range of smectite content may cause a relative uncertainty
455 of up to 70% for samples with low smectite content. We also show that XRD
456 on randomly oriented powders is not sufficient for smectite quantification in
457 samples containing other disordered clay minerals (including smectite-bearing
458 mixed-layers) and/or chlorite. We establish that the fraction of Cu-trien con-
459 sumed at the end of the reaction needs to be optimized in order to minimize
460 the total uncertainty of the CEC measurement. Instrument uncertainty and
461 systematic "partial exchange" error are anti-correlated with varying fraction of
462 Cu-trien consumed. We suggest that a value of 30% for this fraction is optimal,
463 as a rule. Finally, we show a linear correlation between the CEC, measured with
464 an adequate Cu-trien consumption, and the smectite weight fraction determined
465 by XRD, for 24 samples containing smectite as the only swelling clay mineral.
466 Our study provides the geothermal industry with a simple method to quantify
467 the smectite weight fraction (pure smectite or expandable layers in mixed-layer
468 clays) of powders from all kinds of altered volcanic rocks. Different spectropho-
469 tometric back-titration methods, using for example the Cobalti-hexamine (III)
470 molecule, can be used in the same manner for smectite quantification, since a
471 whole range of thermodynamic constants are considered for the cation exchange

472 reaction.

473 5 Acknowledgments

474 L.L. thanks Sigurdur Sveinn Jónsson, Helga Margrét Helgadóttir and Bjarni
475 Gautason for their help with identifying primary and alteration minerals in
476 XRD patterns, thin sections and microscopic observations. L.L. thanks Heimir
477 Ingimarsson, Christina Guenther and Ester Inga Eyjólfsdóttir for their help
478 with the CEC measurements, as well as Iwona Monika Galezka and Kristinn
479 I. Gudmundsson for ICP measurements and discussion of the results. The au-
480 thors thank Christophe Nevado, Doriane Delmas and Khaled Oubellouch for
481 high-quality polished thin sections and Jacinthe Caillaud for electron probe
482 data collection and analysis. The authors are also grateful to Landsvirkjun,
483 and especially Ásgrímur Gudmundsson, for providing rock samples used in this
484 work. Finally, the authors thank editor Halldor Armansson, as well as Reiner
485 Dohrmann and another anonymous reviewer for their remarks and suggestions,
486 which very much helped improve the manuscript.

A Effect of preferred orientation on X-ray diffraction patterns: the case of heulandite

The effect on XRD patterns of preferred orientation when samples are back-loaded onto sample holders, is illustrated in Figure A.1. The relative intensity of the heulandite peak at low angle (about $10^\circ 2\theta$), compared to the other peaks, is much higher when sample is back-loaded. The residuals at the end of refinement (gray signal under each pattern) are also higher in this case.

Figure A.1: Effect of preferred orientation on X-ray diffraction pattern for a sample (L02) containing a large amount of heulandite (zeolite). The upper pannel shows the diffraction pattern when the powder is carefully grained and front-loaded. The lower pannel shows the diffraction pattern for the exact same powder but back-loaded. The diffraction peak of heulandite at angle $10^{\circ} 2\theta$ is four times higher in the lower panel and cannot be correctly fitted.

910 C More details about the CEC protocol and the 911 sources of uncertainty

912 C.1 Preparation of Cu-trien solutions and calibration of 913 the spectrophotometer

914 Exchange solutions are prepared by mixing copper sulphate $CuSO_4$ and the
915 organic compound tri-ethylene-tetramine "trien", in stoichiometric proportions,
916 in a 1 L volumetric flask. The theoretical concentration of the stock solution is
917 calculated following Equation 18.

$$C_{stock} = \frac{\min(\frac{m_{CuSO_4}}{M_{CuSO_4}}; \frac{m_{trien}}{M_{trien}})}{V_{tot}} \quad (18)$$

918 where m_{CuSO_4} and m_{trien} are the masses of $CuSO_4$ and "trien", in g, M_{CuSO_4}
919 and M_{trien} are the molar masses of $CuSO_4$ and "trien", in g/mol and V_{tot} is
920 the total volume of the solution, in L. The masses of $CuSO_4$ and "trien" are
921 calculated to obtain a final concentration of 0.01 M Cu-trien (e.g. $m_{CuSO_4} =$
922 1.6114 g (anhydrous) and $m_{trien} = 1.4941$ g).

923 The complex "Cu-trien" is formed by stoichiometric reaction between the
924 two compounds, so that the quantity of Cu-trien formed (in mol) corresponds
925 to the quantity of the compound initially present in lesser quantity, the "limiting
926 reactant". According to Stanjek and Künkel (2016), one has to avoid using an
927 excess of "trien" in the preparation, due to a possible complexation of trien
928 with the interlayer cations of smectite (e.g. Ca, Mg) that would prevent a later
929 exchange with Cu-trien. Since the "trien" compound (from Sigma-Aldrich) has
930 a purity of ≥ 97 % (see also in Ammann, 2003; Stanjek and Künkel, 2016), and
931 the masses are calculated as if trien were 100% pure, $CuSO_4$ is theoretically in
932 excess in our preparation.

Table C.1: Comparison of theoretical (conc. theo.) and ICP-measured Cu concentration (conc. ICP) in six Cu-trien solutions and two $CuSO_4$ solutions. The first six rows correspond to Cu-trien solutions whose ICP-measured Cu concentration are used for the calibration curve in Figure C.1. The two last rows correspond to $CuSO_4$ solutions, prepared with pentahydrated and anhydrous solids.

Solution	Conc. ICP mol/L	Conc. theo mol/L	Err
Cu-trien StdA	3.45E-04	3.59E-04	4%
Cu-trien StdB	1.04E-03	9.99E-04	-4%
Cu-trien StdD	1.63E-03	1.68E-03	3%
Cu-trien StdE	2.63E-03	2.53E-03	-4%
Cu-trien 1:6 a	1.58E-03	1.52E-03	3%
Cu-trien 1:6 b	1.50E-03	1.52E-03	-2%
CuSO4 (pentahyd.)	1.01E-02	1.00E-02	1%
CuSO4 (anhyd.)	9.73E-03	1.00E-02	-3%

933 Most of the exchange solutions are prepared with anhydrous $CuSO_4$. Since
 934 anhydrous $CuSO_4$ is an hygroscopic compound and might have slightly rehy-
 935 drated during storage, we measure the Cu concentration of both Cu-trien and
 936 $CuSO_4$ solutions by ICP (calibrated with a standard for Copper at the wave-
 937 length 324.754 nm). We compare the measured concentrations to the theoret-
 938 ical solutions, calculated as if it were perfectly anhydrous (Table C.1). ICP
 939 results indicate that the theoretical Cu concentrations in the $CuSO_4$ solutions,
 940 prepared with anhydrous and pentahydrated solid $CuSO_4$, are overestimated
 941 by 2.7% and underestimated by 0.8%, respectively. The relative difference in
 942 Cu concentration of 6 Cu-trien solutions, all prepared with anhydrous $CuSO_4$,
 943 carries between -4% and 4% (Table C.1). This indicates that no systematic error
 944 in the Cu concentration (due to possible rehydration and thus increase of the
 945 molar mass) shall be taken into account in the calculations.

946 Four independent Cu-trien stock solutions and respective dilutions are used
 947 for calibrating the spectrophotometer. This set of solutions includes the Cu-
 948 trien solutions whose Cu concentration is measured by ICP (Table C.1). It also
 949 includes two Cu-trien solutions directly prepared with the two $CuSO_4$ solutions
 950 measured by ICP beforehand. In these cases, the mass of solution is weighted
 951 and a mass of "trien" corresponding to a stoichiometric ratio between Cu and

952 trien is mixed with deionized water and added to the copper sulphate solution
 953 in a 1 L volumetric flask.

954 The corresponding calibration curve, presented in Figure C.1, shows that the
 955 multiplicative factor L between absorbance and Cu-trien concentration ($A =$
 956 $L[Cu - trien]$) is determined with satisfying accuracy ($L = 145.4 \pm 0.9$ L/mol).

Figure C.1: Calibration curve (absorbance versus theoretical concentration) for the Cu-trien exchange solution. The fitted line is a linear function with an intercept forced to 0. The slope L of the linear fit and the regression coefficient are given on the figure. The absorbance is always measured at 578 nm.

957 C.2 Contact time with Cu-trien

958 A test is carried out on sample L126 to evaluate whether longer contact times
 959 with Cu-trien might lead to increased exchange. The CEC measured after 5
 960 and 60 minutes are 53.4 ± 0.7 meq/100g and 53.1 ± 0.7 meq/100g, respectively.
 961 We consider the difference between these two numbers not significant, which
 962 confirms that 5 minutes is a sufficient time for this type of samples.

963 D Water content and CEC correction

964 CEC measurements are carried out on rock samples dried at room tempera-
965 ture. The CEC values presented in this study do not include a correction for
966 the water content in the samples. In particular, the slope presented in Figure
967 7 corresponds to the average CEC of smectite in samples dried at room tem-
968 perature, i.e. containing up to 7% of bound water molecules. We present in
969 Table D.1 measurements of the water content and corrected CEC values for all
970 samples presented in this study. The water loss is quantified by drying a given
971 mass of each sample at 105°C. Figure D.1 shows the correlation between CEC,
972 as corrected for the water content, and smectite content. This slope results in
973 a CEC of pure smectite slightly higher than when considering the uncorrected
974 CEC values.

Table D.1: Water loss at 105°C and correction of the CEC values to take into account the water content.

ID	Water content wt. %	CEC (no correction) meq/100g (room T)	CEC corrected meq/100g (105 °C)
