## ABSTRACT

Gamma-ray binaries emit most of their radiated power beyond  $\sim 10$  MeV. The non-thermal emission is thought to arise from the interaction of the relativistic wind of a rotation-powered pulsar with the stellar wind of its massive (O or Be) companion star. A powerful pulsar creates an extended cavity, filled with relativistic electrons, in the radiatively driven wind of the massive star. As a result, the observed P Cyg profiles of ultraviolet (UV) resonant lines from the stellar wind should be different from those of single massive stars.

We propose to use UV emission lines to detect and constrain the colliding wind region in gamma-ray binaries. We compute the expected orbital variability of P Cyg profiles depending upon the interaction geometry (set by the ratio of momentum fluxes from the winds) and the line of sight to the system. We predict little or no variability for the case of LS 5039 and PSR B1259–63, in agreement with currently available *Hubble Space Telescope* (*HST*) observations of LS 5039. However, variability between superior and inferior conjunction is expected in the case of LS I+61 303.

**Key words:** line: profiles – stars: winds, outflows – X-rays: binaries.

## 1 INTRODUCTION

There are now five gamma-ray binaries detected in high-energy (HE;  $> 100$  MeV) and very high energy (VHE;  $> 100$  GeV) gamma-rays: PSR B1259–63, LS 5039, LS I+61 303, HESS J0632+057 and 1FGL 1018.6–5856. All contain a massive star and a compact object, and emit most of their power at energies above 10 MeV (for recent reviews see e.g. Hill et al. 2011; Paredes 2011). The observed orbitally modulated HE and VHE gamma-ray emission indicate that particles are accelerated to multi-TeV energies within or close to the binary. The available observations in radio, X-rays and gamma-rays seem to favour a scenario in which particles are accelerated in the wind of a young pulsar (Maraschi & Treves 1981; Dubus 2006) rather than in the jet of a microquasar (Romero, Christiansen & Orellana 2005; Dermer & Böttcher 2006; Paredes, Bosch-Ramon & Romero 2006). The pulsar model is known to be operating in the case of PSR B1259–63 (Tavani, Arons & Kaspi 1994; Kirk, Ball & Skjaeraasen 1999). The latest searches for radio pulsations in LS 5039 and LS I+61 303 yielded no positive result (McSwain et al. 2011), thus the presence of a wind collision region and pulsar remains to be proven in all remaining gamma-ray binaries.

A common denominator to all known gamma-ray binaries is a massive companion star (O or Be type). The massive star loses mass via a strong, hot, radiatively driven wind at a rate that can be higher than  $10^{-7} M_{\odot} \text{ yr}^{-1}$  (Howarth & Prinja 1989). Ultraviolet (UV) resonant spectral lines formed in the wind are indicators of its velocity and mass-loss rate. If the wind density is large enough, the lines have a P Cygni profile consisting of a violetshifted absorption component and redshifted emission component. The P Cyg profiles form via absorption and scattering of photospheric continuum emission in the expanding, spherically symmetric stellar wind (see Section 2.1).

The P Cyg line profiles from massive stars in a binary system with another massive star (e.g. O+O or WR+O) differ from those of a single star and are variable with orbital phase. The difference is caused by dynamical interactions between the two stellar winds and radiative feedback (e.g. wind ionization, radiative braking) between stellar winds and radiation field of the companion star. The variability of P Cyg profiles in massive star binaries was modelled numerically by Stevens (1993). The results showed that P Cyg profiles have high diagnostic value for learning on the existence and the parameters of the colliding winds region.

UV line variability is also expected in high-mass X-ray binaries where an X-ray source ionizes the surrounding wind regions creating an extended Strömgren zone. The fully ionized plasma does not

\*E-mail: aszostek@slac.stanford.edu

have any spectral transition, therefore the zone does not take part in resonant scattering, and the observed P Cyg line profiles should be different from that in the case of single stars. This effect was predicted by Hatchett & McCray (1977) and studied in detail by van Loon, Kaper & Hammerschlag-Hensberge (2001).

We propose that line-profile variability could be observed in the UV spectra of gamma-ray binaries within the framework of the pulsar wind scenario, where the relativistic wind of the pulsar creates a cavity in the companion stellar wind (see Section 2.2). The cavity is filled with relativistic particles which do not take part in resonant scattering of UV photons. Only the wind outside the cavity is responsible for the P Cyg profile. The cavity is described by its size (which increases with the parameter  $\eta$  – see Section 2.2 – and thus opening angle), and by location with respect to the line of sight. With an increasing size of the cavity, line profiles are expected to differ more from that of a single star. Concurrently, because the jets constitute narrow collimated outflows from the vicinity of the compact object, we do not expect the creation of the extensive cavity or significant wind alterations in the microquasar scenario. The presence or absence of line-profile variability puts constraints on a size and location of the cavity. If changes in the line profile along the orbit are detected, a microquasar scenario can be rejected with high certainty.

In this article we study if and how the observed line profiles can vary in gamma-ray binaries in the framework of pulsar wind scenario. We constructed a semi-analytical model composed of a massive star wind with a cavity. We describe the model in Section 2. In Section 3 we show how the line profiles change with the shape and location of the cavity. In Section 3.3 we apply the results to gamma-ray binaries LS 5039, PSR B1259–63 and LS I+61 303. In Section 4 we discuss our results and present the conclusions.

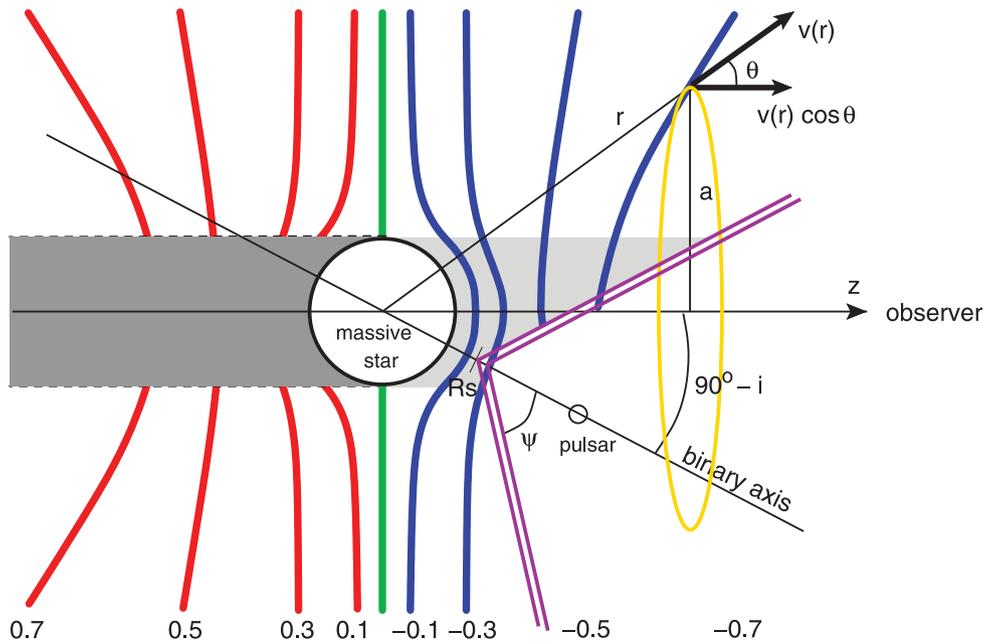

## 2 MODEL

### 2.1 Formation of P Cygni profiles

In most general terms, the P Cyg line profiles form via line scattering of photospheric photons in the hot expanding stellar wind of a massive star. The absorption line is formed when the photons emitted from a photosphere are scattered away from the line of sight by the stellar wind located in front of stellar disc and moving towards the observer (light grey area of Fig. 1). The absorption component extends between Doppler velocities  $-v_\infty$  and 0. The emission line is created by the wind which surrounds the stellar disc (as seen by the observer) and which scatters the photospheric radiation into the line of sight, creating an emission line. If there was no wind, this radiation would never reach the observer. The emission line extends between Doppler velocities  $-v_\infty$  and  $v_\infty$ . The radiation scattered behind the star (dark grey region of Fig. 1) does not reach the observer. A superposition of the absorption and emission component creates the characteristic observed P Cyg profile (Lamers & Cassinelli 1999).

In more detail, the photons of frequency  $\nu$  are scattered into or of the line of sight by wind elements moving with respect to the observer with a velocity  $v_z = v(r)\cos\theta = c(\nu - \nu_0)/\nu_0$  where  $\nu_0$  is a rest-frame frequency of a given resonant atomic transition. All the wind elements moving with the same velocity  $v_z$  are distributed along a surface  $S_\nu$ . The shape and emission of each  $S_\nu$  are symmetrical with respect to the line of sight. A cross-section across several of such constant-velocity surfaces, corresponding to different frequencies, is shown in Fig. 1 as solid, blue, red and green lines.

A cavity created by a pulsar wind may crop some of the constant-velocity surfaces, breaking the axial symmetry and changing the flux

**Figure 1.** Section through a generic gamma-ray binary, cut along the binary axis and perpendicular to the orbital plane. Observer is to the right at infinity and sees the binary with an inclination of  $i \simeq 60^\circ$ . Solid curves represent surfaces of constant wind velocity component towards the observer. The velocities in units of  $v_z/v_\infty$  are marked below each curve. Negative velocities are in blue, positive in red and green refers to zero velocity. Light grey shaded area marks the extent of the absorption zone. Dark grey area is the occulted wind region, which does not contribute to the final profile. Double solid line corresponds to the CD with  $\eta < 1$ . The area to the right of the CD is the pulsar wind cavity, filled with relativistic electrons which do not take part in resonant scattering of UV photons. The yellow ellipse is a cross-section of one of the emission surfaces  $S_\nu$ .

received by the observer from the surfaces. The level of modification depends on the shape and location of the pulsar wind cavity with respect to the observer.

## 2.2 The shape and location of a cavity

The cavity is bounded by the colliding wind region, composed of two termination shocks separated by a tangential contact discontinuity (CD; double solid line in Fig. 1). In the following we ignore the presence of the shocked winds and identify the shape of the pulsar wind cavity with the shape of CD. The shape of the cavity can be approximated by a conical surface symmetric with respect to the binary axis. Its vertex is located at the stagnation point, where the ram pressures of the two winds balance:

$$p_* = \frac{\dot{M}v_{R_s}}{4\pi R_s^2} = \frac{\dot{E}}{4\pi c(s - R_s)^2} = p_p, \quad (1)$$

where  $R_s$  is the distance of the stagnation point from the star centre,  $p_*$  and  $p_p$  are (respectively) the stellar and pulsar wind ram pressures at the stagnation point,  $s$  is the binary orbital separation at a given orbital phase,  $\dot{M}$  is the stellar wind mass-loss rate,  $\dot{E}$  is the pulsar spin-down power and  $v_{R_s} = v(R_s)$  is the stellar wind velocity at the radial distance  $R_s$  from the star's centre. For massive star it is given by a  $\beta$ -velocity law (Castor, Abbott & Klein 1975)

$$v(r) = v_\infty \left(1 - \frac{R_* r_0}{r}\right)^\beta, \quad (2)$$

where  $r_0 = 1 - (v_0/v_\infty)^{1/\beta}$ ,  $v_0$  is the initial wind velocity,  $v_\infty$  is the wind terminal velocity,  $R_*$  is the stellar radius and  $\beta \approx 1$ .

The size of the cavity can be parametrized by the asymptotic opening angle of the cavity  $\psi$ , which in the conical approximation equals to half the vertex angle. We use the phenomenological relation derived from hydrodynamical simulations by Bogovalov et al. (2008):

$$\begin{aligned} \psi &= 28.6(4 - \eta^{2/5})\eta^{1/3} \quad \text{for } \eta \leq 1, \\ \psi &= 171.5 - 28.6(4 - \eta^{-2/5})\eta^{-1/3} \quad \text{for } \eta \geq 1, \end{aligned} \quad (3)$$

where  $\psi$  is measured in degrees and where

$$\eta = \frac{\dot{E}}{\dot{M}v_{R_s}c} \quad (4)$$

is the ratio of pulsar to stellar wind ram pressures at  $R_s$ . When  $\eta < 1$  then  $\psi < 90^\circ$ , the stellar wind dominates over the pulsar wind and the wind-free cavity is created around the pulsar as in Fig. 1. When  $\eta > 1$  then  $\psi > 90^\circ$ , the pulsar wind dominates over the stellar wind and the conical CD encloses the star, efficiently blocking the wind from expanding into space around the binary. In this case the volume of the cavity can be larger than the volume of the expanding stellar wind. For low enough  $\eta$ , the stellar wind may also be prevented from freely expanding backwards by a reconfinement shock (Bogovalov et al. 2008). Numerical simulations are then required to model the interaction region properly – this is not taken into account here. Finally, no stable balance is possible when  $\eta$  becomes very high: the pulsar wind then rams into the stellar surface (Harding & Gaisser 1990), quenching the stellar wind over at least part of one hemisphere.

For a given orbital phase, the location of the pulsar wind cavity can be parametrized using only  $R_s$  and the angle  $\alpha$  between the line of sight and the binary axis:

$$\alpha(i, t, \omega) = \cos^{-1} [\sin i \cos(t - \omega)], \quad (5)$$

where  $t$  is the pulsar true anomaly (pulsar angular distance from periastron) and  $\omega$  is the angle of the line of nodes of the orbit. Small values of  $\alpha$  correspond to large inclination angles and orbital phases close to inferior conjunction (INFC; when the pulsar is in between the massive star and the observer). The maximum value is reached at superior conjunction (SUPC; when the pulsar is behind the star as seen by the observer) with  $\alpha = 180^\circ$  and  $i = 90^\circ$ .

## 2.3 Line-profile calculations

We followed Lucy (1971, hereafter L71) to compute the line profile from the stellar wind of a massive star with a radius  $R_*$  and a stellar wind terminal velocity  $v_\infty$ . We model only single line profiles and do not consider line doublets where multiline scattering takes place. We assumed that the resonant transition  $\nu_0$  is possible in the entire volume of the wind, as opposed to the situation where line transition is only possible in a certain wind layer due to the ionization gradient. We assume that the line opacity changes only due to changes in the gas density and do not take ionization effects into account. Here, we model line-profile variability only for saturated profiles created in optically thick wind, but the qualitative results are also applicable to unsaturated lines from optically thin winds.

To account for the presence of the pulsar wind cavity in the stellar wind, we modified equation (43) of L71 which in its original form returns a normalized flux at frequency  $\nu$  emitted by a corresponding constant-velocity surface  $S_\nu$ . The modified equation (43) has the form

$$\begin{aligned} F_{\nu_0}(\nu) &= \frac{2}{R_*^2} \int_{R_*}^{\infty} \{f_\nu(r)\Phi_\nu(\kappa, r, \nu) + [1 - f_\nu(r)]\Phi_\nu(0, r, \nu)\} \\ &\quad \times H(1 - \mu^2) \times \frac{r}{v(r)} \frac{\partial v_z}{\partial z} r \, dr, \end{aligned} \quad (6)$$

where we assumed that the continuum flux equals 1,  $\mu = \cos\theta$ ,  $H$  is the Heaviside function,  $\Phi$  is given by equation (44) in L71, whereas the last term is given by equation (42) in L71.  $\kappa$  is an absorption coefficient set to an arbitrary value which gives saturated line profiles. The integral in equation (6) includes a function  $f_\nu$  that is a fraction of a circular cross-section of  $S_\nu$  (at  $r$  perpendicular to the line of sight), which is outside of the pulsar wind cavity. An example cross-section of  $S_\nu$  for which  $v_z = -0.7v_\infty$  is shown as yellow ellipse in Fig. 1. The function  $f_\nu(r)$  depends on the shape of the cavity via  $\eta$  and its location with respect to the observer via  $R_s$  and  $\alpha$ .  $f_\nu(r)$  is calculated numerically for each binary configuration and frequency.

In order to quantify the difference between P Cyg profile  $P(\nu)$  of the same resonant line  $\nu_0$  but for winds with different cavities, we introduce the profile area  $A$ , defined as

$$A(\eta, R_s, \alpha) = \int_{-\nu_\infty}^{\nu_\infty} |P(\nu) - 1| d\nu, \quad (7)$$

which is simply a sum of flux within the emission line above continuum and flux removed from continuum by absorption. In the following we will use  $A_0$  to denote a profile area normalized by a profile area of a single star.

A spectral resolution of Cosmic Origin Spectrograph (COS) instrument onboard the *Hubble Space Telescope* (HST) in the 900–1450 Å wavelength range and using bright object aperture is  $R = 3200$ –4200 (Osterman et al. 2011). This corresponds to 40–90 km s<sup>-1</sup> (2–6 per cent of  $v_\infty$  depending on spectral type). Assuming that the line is fully saturated, we estimate that for this resolution, a change in profile can be detected if a ratio of profiles' areas changes at least by 0.05–0.1.

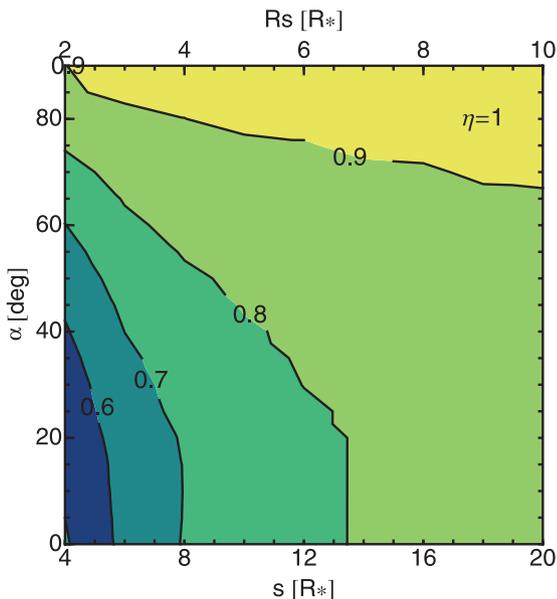

### 3 RESULTS

#### 3.1 Parameter survey

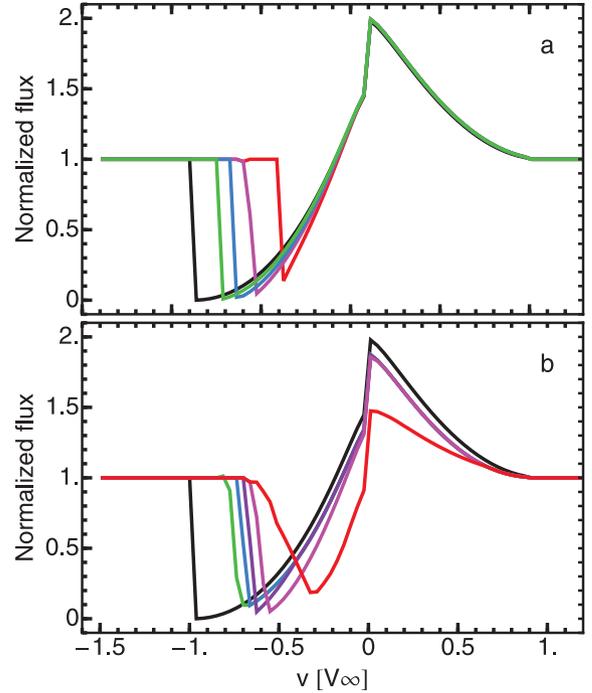

We chose to study the variations in line profiles by changing  $\eta$ ,  $\alpha$  and  $s$  (or  $R_s$ ). A set of three parameters is sufficient to describe all possible configurations. We successively freeze one of the parameters and show contour plots of  $A_0$  as a function of the other two. Note that the physical length scale is set by  $R_*$ .

Fig. 2 shows  $A_0$  as a function of  $s$  and  $\alpha$  when  $\eta = 1$ , which implies  $\psi = 90^\circ$  and  $R_s = 0.5s$ . The line profile from a gamma-ray binary differs more from that of a single star when the cavity is closer to the star (smaller  $R_s$  in units of  $R_*$  or, equivalently, smaller  $s$ , implying shorter orbital periods) and when the axis of the cavity is close to the line of sight (low  $\alpha$ ). Example profiles for  $\alpha = 0$  are shown in Fig. 3(a). When the cavity moves in closer to the star, the stellar wind is prevented from reaching high velocities in the absorption zone (Fig. 1). Photons that would have been scattered away from the line of sight can then reach the observer unaltered, which explains the narrower absorption trough. For  $\eta = 1$ , the red emission component of the line profile barely changes since it arises from regions unaffected by the cavity.

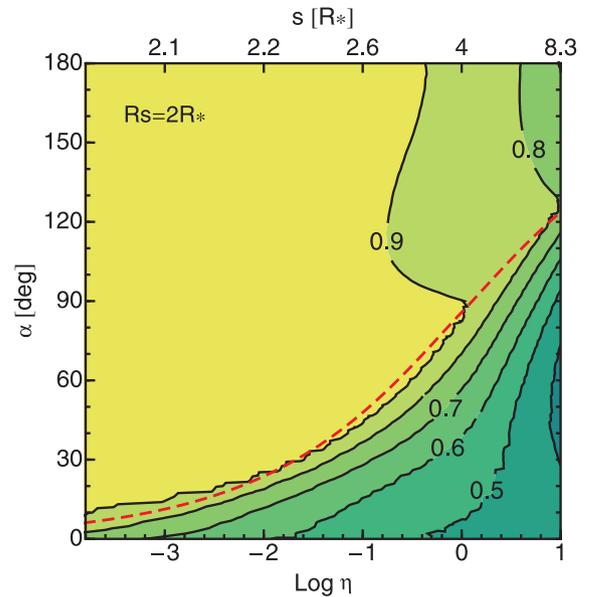

Fig. 4 shows  $A_0$  as a function of  $\eta$  and  $\alpha$  when  $R_s = 2R_*$ . Note that keeping  $R_s$  fixed implies that the pulsar power increases with  $\eta$  (hence  $s$ ), up to  $\dot{E} \sim 10^{38} \text{ erg s}^{-1}$  when  $\eta = 10$  and assuming  $\dot{M} = 10^{-7} M_\odot \text{ yr}^{-1}$ . The line profile is increasingly modified when  $\eta$  becomes high (i.e. wider cavity opening angle  $\psi$ ). The line profile is most sensitive to the presence of the cavity when  $\alpha < \psi$ , i.e. when the line of sight passes through the cavity for some orbital phases. For  $\alpha > \psi$ , the profile is only weakly sensitive to changes of  $\alpha$  or  $\eta$ . When  $\alpha < \psi$ , changes in the blue absorption line (created by the wind located along the line of sight) are responsible for the strong variations in  $A_0$ . Example profiles are shown in Fig. 3(b) with  $R_s = 3R_*$  and  $\alpha = 0^\circ$ . The red emission part of the line is modified

**Figure 2.** Contour plot of the normalized profile area  $A_0$  as a function of the binary separation  $s$  and the angle  $\alpha$  (between the cavity axis and line of sight). Here,  $\eta = 1$  is fixed, which implies that  $\psi = 90^\circ$  and  $R_s = 0.5s$  are also fixed. Line profile increasingly resembles that of a single star ( $A_0 = 1$ ) with increasing  $s$  and  $\alpha$ .

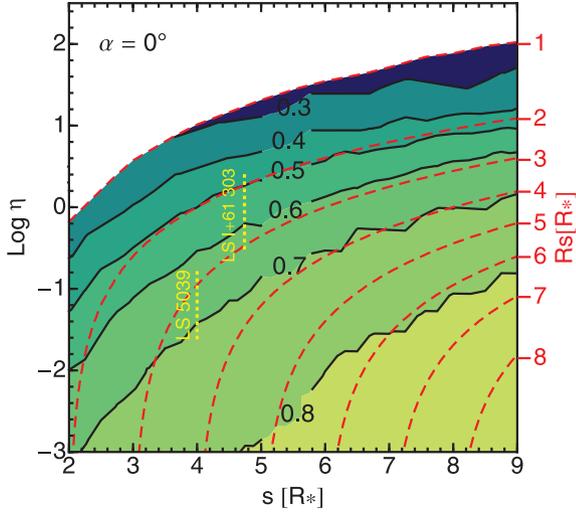

**Figure 3.** P Cyg profiles for different binary configurations. Top:  $\eta = 1$ ,  $\alpha = 0$  are fixed and the binary separation  $s$  is changed. Profiles shown  $s = \infty$  (single star, black,  $A_0 = 1$ ),  $s = 4R_*$  (red,  $A_0 = 0.6$ ),  $s = 6R_*$  (magenta,  $0.7$ ),  $s = 8R_*$  (blue,  $0.8$ ) and  $s = 13R_*$  (green,  $0.9$ ). Bottom:  $R_s = 3R_*$  and  $\alpha = 0$  are fixed and  $\eta$  is changed (equivalent to varying cavity opening angle  $\psi$ ). Profiles correspond to  $\eta = 0.02$ ,  $\psi = 30^\circ$  (green,  $A_0 = 0.72$ );  $\eta = 0.23$ ,  $\psi = 60^\circ$  (blue,  $0.68$ );  $\eta = 1$ ,  $\psi = 90^\circ$  (violet,  $0.65$ );  $\eta = 4.5$ ,  $\psi = 120^\circ$  (pink,  $0.65$ ) and  $\eta = 50$ ,  $\psi = 150^\circ$  (red,  $0.5$ ).

**Figure 4.** Contour plot of the normalized profile area  $A_0$  as a function of  $\eta$  and  $\alpha$  with  $R_s = 2R_*$  fixed. The corresponding binary separation  $s$  is plotted at the top of the figure. The red dashed line shows  $\alpha = \psi$ .

when  $\psi$  (hence  $\eta$ ) is very high, disrupting the wind well beyond the absorption zone.

Finally, Fig. 5 shows  $A_0$  as a function of  $\eta$  and  $s$  when  $\alpha$  is held fixed at zero. The general trends are in agreement with those shown

**Figure 5.** Contour plot of the normalized profile area  $A_0$  as a function of binary separation  $s$  and  $\eta$  for  $\alpha = 0^\circ$  fixed. Constant values of  $R_s$  in this parameter space are shown as dashed lines. The white region at the top of the plot is where the wind interaction region collides with the stellar surface. The expected parameter range for LS 5039 and LS I+61 303 is also shown.

in Figs 2–4.  $A_0$  decreases with increasing  $\eta$  and decreasing  $s$ . The dependence on the separation  $s$  is relatively weak. Instead, the  $A_0$  contours follow closely the contours of constant  $R_s$ , as expected based on Fig. 2. Fig. 5 shows that deviations from a single-star profile can be observed when  $R_s \lesssim 6R_*$ , assuming the most favourable binary configuration ( $\alpha = 0^\circ$ ). The white area at the top of the plot covers the parametric region where the wind collision region intercepts the stellar surface (see Section 2.2).

These results are in very good agreement with the calculations of Stevens (1993) for binaries composed of two massive stars, in particular with their model 1b. The profile variability shown in fig. 2(b) of Stevens (1993) can be directly compared with our Fig. 3(a). Our calculations apply to any inclination, orbital phase and shape of the cavity.

### 3.2 Survey limitations

The line profile strongly depends on the cavity opening angle  $\psi$ . Gayley (2009) derived a relation between  $\eta$  and the asymptotic value of  $\psi$ , which is different from that used here, based on other assumptions about the flow in the shocked region. The opening angles under these assumptions are larger from the ones given by equation (3). The difference is about  $10^\circ$  for  $0.1 < \eta < 1$  and increases to  $\sim 15^\circ$  for smaller  $\eta = 0.005$ . Based on Fig. 4, we estimate that in the most favourable case, when  $\alpha = 0^\circ$ , the  $15^\circ$  increase of  $\psi$  leads to a decrease in  $A_0$  of  $\approx 0.1$ ; hence it is of minor consequences to our results. Improved accuracy in predicting line profiles is more likely to require advanced stellar wind models and numerical simulations of the pulsar wind interaction with stellar wind.

In our calculations we assumed a spherical symmetry of the pulsar wind momentum distribution. The simulations of pulsar winds from high-velocity neutron stars interacting with the interstellar medium (ISM) provide insight on the possible impact of a latitudinal variation of pulsar wind on the shape of the interaction surface. The results of the simulations performed by Vigelius et al. (2007)

show that while some changes in the structure of the interaction region close to the pulsar are possible, the overall geometry remains mostly the same and is determined principally by  $\dot{E}/c$ . The present study is far from the level of detail where it would be necessary to take these effects into account.

Three out of five known gamma-ray binaries contain a massive Be companion star. The class of stars is known for their highly anisotropic winds composed of a fast, tenuous polar wind and a dense Keplerian equatorial disc. The interaction of the pulsar wind with the equatorial disc can cause strong variations in momentum ratio  $\eta$  and disturbance of the global interaction surface (Okazaki et al. 2011). The shape of the pulsar wind cavity during disc passage and its impact on the UV lines are uncertain and cannot be addressed by our model.

### 3.3 Application to known systems

We apply our model to the gamma-ray binaries with the best known parameters: PSR B1259–63, LS 5039 and LS I+61 303. We compare line profiles at conjunctions (i.e. at minimum and maximum value of  $\alpha$  for any given orbit) in order to test whether a pulsar wind cavity could be detected.

#### 3.3.1 PSR B1259–63

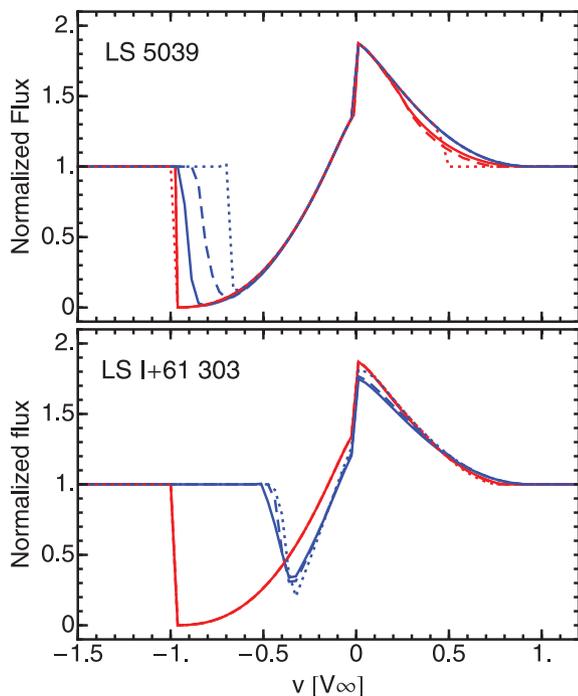

This is the only gamma-ray binary known to contain a pulsar (spin-down power  $\dot{E} = 8 \times 10^{35} \text{ erg s}^{-1}$ ). The companion is a Be star, which has a fast, tenuous polar wind and a slow, dense equatorial disc wind. It is the polar wind that is responsible for the P Cyg profile.

The polar wind mass-loss rate in PSR B1259–63 is about  $\dot{M}_p = 1 \times 10^{-7} M_\odot \text{ yr}^{-1}$ , following Vink, de Koter & Lamers (2000) using the stellar parameters from Negueruela et al. (2011). The corresponding value of  $\eta$  is  $\sim 10^{-2}$ . For this value of  $\eta$  and for  $i \lesssim 25^\circ$  (Negueruela et al. 2011),  $\alpha > \psi$  and we do not expect to see changes in line profile (see Fig. 4 and Section 3.1).

#### 3.3.2 LS 5039

UV observations of LS 5039 at two orbital phases, 0.41 (close to INFC) and 0.63 (close to apastron), did not reveal any changes in the P Cyg line profiles (McSwain et al. 2004). We set constraints on the binary parameters from the lack of variability.

The value of  $\eta$  depends on the balance between the stellar and (putative) pulsar wind, but the parameters of the latter are unknown in LS 5039. Szostek & Dubus (2011) estimated a maximum value of  $\eta_{\text{max}} = 0.6$  at periastron that, based on equations (1) and (3), corresponds to  $\psi \simeq 75^\circ$  and  $R_s = 1.2R_*$ . For higher values of  $\eta$ , the pulsar wind impinges directly on the stellar surface, disrupting the stellar wind over much the pulsar-facing side (the pulsar is only 1–3 stellar radii away from the surface) – which is excluded by the observations. With  $\dot{M} = 10^{-7} M_\odot \text{ yr}^{-1}$ ,  $v_\infty = 2.4 \times 10^8 \text{ cm s}^{-1}$ ,  $R_* = 9.3R_\odot$  (Casares et al. 2005) and  $v_0 = 2 \times 10^6 \text{ cm s}^{-1}$ ,  $\eta_{\text{max}}$  is reached for a pulsar with  $\dot{E} \simeq 5 \times 10^{36} \text{ erg s}^{-1}$ , which is higher than in PSR B1259–63 but not unknown among other pulsars (e.g. Kargaltsev & Pavlov 2010). Zabalza, Bosch-Ramon & Paredes (2011) set a comparable upper limit from the absence of strong thermal X-ray emission from the shocked stellar wind. LS 5039 has a mildly eccentric orbit, meaning that  $\eta$  and  $\psi$  decrease and  $R_s$  increases at phases away from periastron. Hence, line profiles calculated with  $\eta = \eta_{\text{max}}$  at periastron give an upper limit on the

**Figure 6.** Expected P Cyg profiles for LS 5039 and LS I+61 303 at two orbital phases (SUPC, red and INFC, blue) assuming  $\eta = \eta_{\max}$  (see text for details) and inclination angles of  $50^\circ$  (solid),  $60^\circ$  (dashed) and  $90^\circ$  (dotted).

orbital variability that can be expected. In this case, the cavity parameters at conjunctions are  $\eta = 0.38$ ,  $\psi = 70^\circ$ ,  $R_s = 1.4R_*$  (SUPC) and  $\eta = 0.17$ ,  $\psi = 55^\circ$  and  $R_s = 2.8R_*$  (INFC). The inclination of the binary is unknown:  $i < 60^\circ$  if the X-ray source is point-like (Casares et al. 2005) but  $i$  can be as high as  $90^\circ$  if the X-ray source is extended (Szostek & Dubus 2011). However, the observed gamma-ray luminosity requires a pulsar spin-down power at least similar to PSR B1259–63, in which case  $\eta \geq \eta_{\min} \approx 0.04$ .

The range of  $\eta$  discussed above is marked in Fig. 5, showing that the expected change in line profile is modest even for the most favourable case  $\alpha = 0^\circ$ . The difference in P Cyg profiles (Fig. 6) between SUPC and INFC for  $\eta = \eta_{\max}$  should be detectable down to  $i \approx 50^\circ$ . From this result and the fact that line profiles of LS 5039 are constant as observed by *HST*, we conclude that  $\eta$  must be much less than  $\eta_{\max}$  or that  $i < 50^\circ$ . There is a degeneracy between the two parameters but the higher the value of  $i$ , the lower  $\eta$  and  $\dot{E}$  need to be to avoid line variability. At high inclination, even small cavities with  $\eta \sim 10^{-3}$  cause an observable ( $A_0 \leq 0.9$ ) modulation of line profiles along the orbit. If  $\eta = \eta_{\min}$ , then variability in the profiles is detectable unless  $i \leq 70^\circ$ . Therefore, we conclude that the absence of variability in the line profiles observed with *HST* requires low values of  $\eta$  if the inclination is high, with an upper limit  $i \leq 70^\circ$ , with higher values of  $\eta$  possible if the inclination is smaller.

### 3.3.3 LS I+61 303

LS I+61 303 also harbours a massive Be star. Romero et al. (2007) suggested that the pulsar wind would dominate over the polar wind ( $\eta > 1$ ) over much of the orbit, creating an extended cavity in the stellar wind. Because the polar wind is less dense (lower  $\dot{M}$ ) than the wind in LS 5039, the line profiles are expected to be weaker

but observable. The *IUE* spectra of LS I+61 303 (generally low dispersion and poor signal-to-noise ratio) obtained between 1978 and 1983 indicate that several emission lines formed in the wind show variability of uncertain nature (Howarth 1983).

Taking the stellar parameters ( $R_* = 10 M_\odot$ ,  $v_\infty = 10^8 \text{ cm s}^{-1}$ ,  $\dot{M} = 10^{-8} M_\odot \text{ yr}^{-1}$ ) and the orbital solution derived by Aragona et al. (2009), we estimate  $\eta_{\max} \approx 4.5$  at periastron, for which  $R_s = 1.3R_*$  and  $\psi = 120^\circ$ . The spin-down power implied is  $\dot{E} \simeq 4 \times 10^{36} \text{ erg s}^{-1}$ . The cavity parameters change from  $\eta = 1.5$ ,  $R_s = 4.4R_*$  and  $\psi = 100^\circ$  (SUPC) to  $\eta = 2.5$ ,  $R_s = 1.8R_*$  and  $\psi = 110^\circ$  (INFC). The expected LS I+61 303 profiles at conjunctions are plotted in Fig. 6. In Fig. 5 we also indicate a range of  $\eta$  for values of  $\dot{E}$  between  $8 \times 10^{35}$  and  $4 \times 10^{36} \text{ erg s}^{-1}$  at  $\alpha = 0$ . We expect to see a significant variability of line profiles along the orbit in LS I+61 303 because  $\eta$  is always relatively high in this system for plausible values of  $\dot{E}$ . If the pulsar interacts with the Be disc instead of the polar wind at some orbital phases, then  $\eta$  is expected to be much lower than  $\eta_{\max}$  due to the increased density, resulting in an increase of  $A_0$ . This may result in some of the unexplained UV variability although this is difficult to assess with the currently available data.

## 4 CONCLUSIONS

We modelled the line-profile orbital variability due to the presence of a pulsar wind-generated cavity in a gamma-ray binary. The line profiles increasingly differ from those of a single star when the cavity is the largest and located closer to the line of sight, that is for smaller  $R_s$ , larger  $\eta$  and smaller  $\alpha$ . The strong dependence on  $\alpha$  means that significant variations are expected whenever the cavity intersects the wind region responsible for the blueshifted absorption component. The emission component of the P Cyg profile remains steady except for very large values of  $\eta$  (and  $\psi$ ).

We applied our model to the binaries LS 5039, PSR B1259–63 and LS I+61 303. We predict that there is no observable line-profile variability in PSR B1259–63 due to large separation along the orbit and small inclination angle. *HST* UV spectroscopy of LS 5039 did not show a change in line profiles between phases close to INFC and apastron (McSwain et al. 2004). This implies that the inclination is lower than  $50^\circ$  for the estimated maximum  $\eta_{\max} = 0.6$  and not larger than  $70^\circ$  if  $\eta = 0.04$ . For lower values of  $\eta$  the spin-down power of the pulsar is insufficient to explain the gamma-ray luminosity.

Our model calculations predict a significant line-profile modulation in LS I+61 303 if  $\eta > 1$  as argued by Romero et al. (2007). The modulation should be observable even if the binary inclination angle is low. The shape of the cavity maybe drastically changed during disc wind passage, which should be visible as the line profile returns to the single-star profile. Monitoring of line-profile variability with orbital phase in LS I+61 303 could be used not only to learn about the existence and parameters of the pulsar wind cavity, but also to search for signatures of interactions with the equatorial wind of the Be companion. In addition, if changes in the line profile along the orbit are detected, a microquasar scenario can be rejected with high certainty.
