## Introduction:

Odd-hydrogen ( $\text{HO}_x$ ) species such as OH and  $\text{HO}_2$  have a key role in regulating the chemistry of the atmosphere of Mars. This role was first evidenced by the slow recombination rate of the photolysis products of  $\text{CO}_2$  (i.e.,  $\text{CO} + \text{O}$ ), which required a catalytic pathway to maintain a 95%  $\text{CO}_2$  atmosphere on Mars. McElroy & Donahue (1972) and Parkinson & Hunten (1972) demonstrated that the stability of  $\text{CO}_2$  in the Martian atmosphere holds due to reactions of its photolysis products with  $\text{HO}_x$  ( $\text{CO} + \text{OH} \rightarrow \text{CO}_2 + \text{H}$ ), evidencing the importance of these photochemical species in the composition of the atmosphere.

The photochemistry of the martian atmosphere is frequently studied using remote sensing observations of  $\text{O}_3$  (e.g., (Patel et al. (2021); Perrier et al. (2006)),  $\text{CO}$  (e.g., Olsen et al. (2021); Smith et al. (2021)) and  $\text{H}_2\text{O}_2$  (e.g., Clancy et al. (2004); Encrenaz et al. (2008)), all of which are highly sensitive to the abundance of odd-hydrogen and often used as tracers of the  $\text{HO}_x$  chemistry.

Current numerical models of the atmosphere of Mars are able to explain the seasonal and latitudinal variations of these measured chemical tracers, generally showing good qualitative agreements between the measurements and the expectations (e.g., Holmes et al. (2018); Lefèvre (2004)). However, underestimation of the absolute abundances of  $\text{O}_3$  and  $\text{CO}$  suggests that the model representation of  $\text{HO}_x$  oxidation is too efficient, which could be the result of some missing physical or chemical processes in the models, such as the uptake of  $\text{HO}_x$  on water ice clouds (Lefèvre et al., 2021; Lefèvre et al., 2008).

While the abundance of  $\text{HO}_x$  therefore seems crucial to understand the photochemical processes in the martian atmosphere, there is little information from measurements. Clancy et al. (2013) reported the first and only detection of OH on Mars, which consisted of infrared nightglow emissions in the polar winter atmosphere using from CRISM/MRO. On the other hand,  $\text{HO}_2$  has never been detected in the martian atmosphere, with the most constraining upper limit (198 ppbv) being well above the expected abundances in 3D chemical models (Villanueva et

al., 2013).

In this study, we search for infrared spectral signatures of OH and  $\text{HO}_2$  in the atmosphere of Mars using solar occultation measurements by the Atmospheric Chemistry Suite (ACS) onboard the ExoMars Trace Gas Orbiter (TGO). In addition, we analyse the measurements in context with the expected abundances from the Mars Global Circulation Model (GCM) used by the modelling group at the Open University (hereafter OU-GCM).

## ACS solar occultation observations:

ACS is one of the four instruments that comprise the payload of the ExoMars Trace Gas Orbiter. It consists of a suite of three spectrometers sampling different spectral ranges in the infrared: the near-infrared (NIR: 0.7-1.7  $\mu\text{m}$ ), the mid-infrared (MIR: 2.3-4.2  $\mu\text{m}$ ) and the thermal-infrared (TIRVIM: 0.7-17  $\mu\text{m}$ ) (Korablev et al., 2018).

In this work we use the MIR channel, which measures high-resolution spectra ( $\lambda/\Delta\lambda \approx 20,000$ -30,000) and is dedicated to solar occultation observations. In this type of measurements, the Sun is continuously monitored from a tangent altitude of 270 km until it is occulted by the surface. The normalisation of the spectra using the reference solar signal measured at high altitudes ( $>120$  km) allows us to generate a set of transmission spectra at different tangent heights. Solar occultations are especially suitable for the detection of trace gases in planetary atmospheres thanks to the use of the Sun as the light source, which results in high signal-to-noise ratio (SNR), and the long path sampled by the observations.

The dataset analysed in this work comprises all ACS MIR observations made using secondary grating position 3, which measures eight diffraction orders (206 to 213) encompassing a spectral range between 2.78-2.9  $\mu\text{m}$  ( $3448$ - $3597$   $\text{cm}^{-1}$ ). Up to October 2021, there are 151 observations made using this specific position and covering a range between  $L_S = 160$  in Martian Year 35 (MY35) and  $L_S = 60$  in MY36.

## Radiative transfer analysis:

The radiative transfer analysis of the observations

is performed using the NEMESIS algorithm (Irwin et al., 2008), which has previously been applied to the retrieval of isotopic ratios in the atmosphere from ACS solar occultations (e.g., Alday et al. (2021)). The spectral range sampled by ACS MIR secondary grating position 3 includes absorption features by CO<sub>2</sub>, H<sub>2</sub>O, OH and HO<sub>2</sub>, whose absorption cross sections are computed with line-by-line modelling using the spectroscopic parameters from the 2020 edition of the HITRAN database (Gordon et al., 2022). In the case of the H<sub>2</sub>O absorption, the pressure-broadening coefficients are updated based on the laboratory measurements of Devi et al. (2017) and Régalia et al. (2019), suitable for the broadening of the absorption lines in a CO<sub>2</sub>-dominated atmosphere.

Figure 1 shows a forward model indicating the contribution of different gases to the spectra. The biggest challenge for the detection of HO<sub>x</sub> in this spectral range is the removal of the absorption by CO<sub>2</sub>, H<sub>2</sub>O and dust to isolate the weak spectral features of OH and HO<sub>2</sub>. While some of the strongest features of HO<sub>x</sub> in the measured range are found for wavenumbers  $\nu > 3500 \text{ cm}^{-1}$ , the absorption of CO<sub>2</sub> in that spectral range is much stronger than for  $\nu < 3500 \text{ cm}^{-1}$ , which directly impacts the sensitivity of the measurements to these species. Therefore, we select five spectral windows in diffraction orders 206, 207 and 208 to perform our retrievals, as shown in Figure 1.

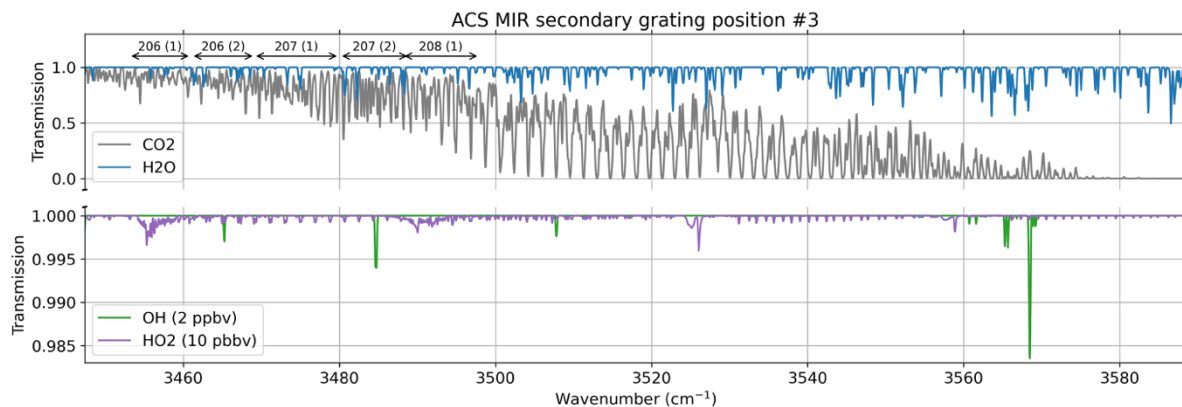

Figure 1: Forward model of a solar occultation observation made with ACS MIR secondary grating position 3 at a tangent altitude of 9 km, showing the contribution from different gases to the spectra, as indicated by the legend. The arrows represent the spectral range covered by each of the spectral windows in diffraction orders 206, 207 and 208 selected for the search of OH and HO<sub>2</sub>.

The retrieval scheme is performed in two steps. First of all, vertical profiles of pressure and temperature are derived from the CO<sub>2</sub> absorption based on the hydrostatic equilibrium equation and a known volume mixing ratio, fitting these features together with the parameters describing the instrument line shape (Alday et al., 2019). Once the pressure and temperature profiles have been calculated, these are

fixed, and a new set of retrievals is run to determine the volume mixing ratios of H<sub>2</sub>O, OH and HO<sub>2</sub>. The retrieved HO<sub>x</sub> abundances are then evaluated based on the ratio between the retrieved abundance and uncertainty  $\sigma = [\text{HO}_x]/[\text{HO}_x]_{\text{err}}$ , where  $\sigma > 3$  indicates a detection. On the other hand, when  $\sigma < 3$ , we define the  $3\sigma$  upper limit using the retrieved uncertainties ( $\text{UL} = 3[\text{HO}_x]_{\text{err}}$ ).

#### Comparison with the OU-GCM:

Once the retrieved dataset for the HO<sub>x</sub> species from the ACS observations is generated, the results will be compared with the expected abundances from the 3D chemical OU-GCM. This model shares physical parameterisations with the GCM from the Laboratoire de Météorologie Dynamique (LMD) (Forget et al., 1999), including the latest update of the photochemical module (Lefèvre et al., 2021).

In addition, the OU-GCM allows the assimilation of spacecraft data into the model. This combination of measurements and model constraints provides the best estimations for the HO<sub>x</sub> abundance with the current physical and chemical parameterisations. The sets of assimilated data are similar to those in Holmes et al. (2022): temperature profiles and dust column from the Mars Climate Sounder on the Mars Reconnaissance Orbiter (MCS/MRO); water and ozone profiles, as well as water and carbon monoxide column abundances from the NOMAD instrument on the ExoMars TGO; temperature and water vapour profiles from ACS/TGO.

As these chemical species are tightly related to the HO<sub>x</sub> chemistry, their assimilation provides useful constraints on the abundance of OH and HO<sub>2</sub> during the time period encompassed by the observations. These predicted model abundances will be compared with the results from the ACS dataset to evaluate if the observations can meaningfully constrain Mars' photochemical models. In addition, the expectations

from the model will also be used to maximise the sensitivity of the ACS measurements by averaging the spectra where the expected abundances in the model are highest.

### Summary and conclusions:

Despite the key role odd-hydrogen species have in regulating the chemistry of the atmosphere of Mars, there is little direct information on the abundance of these from measurements. In this study, we aim to constrain the abundances of OH and HO<sub>2</sub> using solar occultation measurements from the ACS instrument on the ExoMars TGO. These measurements are ideal for the detection of trace species in the atmosphere of Mars thanks to the geometry of the observations.

We search for spectral signatures of these species using measurements made between 2.78–2.9 μm (3448–3597 cm<sup>-1</sup>) between L<sub>S</sub> = 160 in MY35 and L<sub>S</sub> = 60 in MY36. These measurements allow the retrieval of pressure, temperature and water vapour volume mixing ratios during the whole period. In addition, the spectral signatures from OH and HO<sub>2</sub> allow the detection or derivation of upper limits at different altitudes, locations and time periods.

The results from these measurements will be compared with the expectations from the assimilation runs from the OU-GCM to test whether the measurements can meaningfully constrain Mars' photochemical models. In addition, these expectations from the model will also be used to establish a sensitive search at the times/locations when the abundance of HO<sub>x</sub> is highest.
